Pediatric prevention efforts begin with careful monitoring of weight and BMI percentiles at healthcare maintenance visits. Attention to changes in BMI percentiles can alert the pediatric provider to increasing adiposity before the child becomes overweight or obese. All families should be counseled about healthy nutrition for their children because the current prevalence of overweight and obesity in adults is 65%. Therefore, approximately two-thirds of all children can be considered at risk for becoming overweight or obese at some time in their lives. Those who have an obese parent are at increased risk. Prevention efforts begin with promotion of exclusive breastfeeding for 6 mo and total breastfeeding for 12 mo. Introduction of infant foods at 6 mo should focus on cereals, fruits, and vegetables. Lean meats, poultry, and fish may be introduced later in the 1st year of life. Parents should be specifically counseled to avoid introducing highly sugared beverages and foods in the 1st year of life. Instead, they should expose their infants and young children to a rich variety of fruits, vegetables, grains, lean meats, poultry, and fish to facilitate acceptance of a diverse and healthy diet. Parenting matters, and authoritative parents are more likely to have children with a healthy weight than those who are authoritarian or permissive. Families who eat regularly scheduled meals together are less likely to have overweight or obese children. Child health professionals are able to address a child’s nutritional status and to provide expertise in child growth and development.

Child health professionals can also promote physical activity during regular healthcare maintenance visits. Parents who spend some of their leisure time in physical activity promote healthy weight in their children. Beginning in infancy, parents should be cognizant of their child’s developmental capability and need for physical activity. Because television, computer, and video game use can replace health-promoting physical activity, physicians should counsel parents to limit screen time for their children. Snacking during television watching should be discouraged. Parents can help their children to understand that television commercials intend to sell a product. Children can learn that their parents will help them by responsibly choosing healthy foods.

As obesity is determined by complex multifactorial conditions, prevention will take efforts at multiple levels of social organization. One example, EPODE (Ensemble Prévenons l’Obésité Des Enfants), is a multilevel prevention strategy, which began in France and has been adopted by more than 500 communities in 6 countries. The goal is for local environments, daycare centers, schools, recreational settings and families to adopt practices that promote healthy lifestyles for children from birth to 12 yr old. This initiative relies on 4 necessary components: political commitment to change, resources to support social marketing and changes, support services, evidence-based practices. All EPODE sites include monitoring and evaluation. Similar efforts are taking place in the United States. An example of a U.S. community effort is Shape Up Somerville, a citywide campaign to increase daily physical activity and healthy eating in Somerville, MA, which has been ongoing since 2002. This system’s intervention focuses on school health curricula, healthier food in schools and restaurants, safe routes to school, walkable and bikeable streets and worksite wellness. Communitywide programs are important because neighborhood environmental factors (poverty) have been associated with obesity in its residents. Although these efforts have resulted in lower weight gain in older children and adolescents, there is considerable interest in focusing earlier in the life cycle. Beginning obesity prevention during pregnancy and engaging health systems, early childhood programs, and community systems to support healthier life cycles is an approach with tremendous promise.

Bibliography is available at Expert Consult.
Table 47-6  Proposed Suggestions for Preventing Obesity

PREGNANCY
Normalize body mass index before pregnancy.
Do not smoke.
Maintain moderate exercise as tolerated.
In gestational diabetics, provide meticulous glucose control.
Gestational weight gain within the Institute of Medicine (IOM) recommendations.

POSTPARTUM AND INFANCY
Breastfeeding: exclusive for 4-6 mo, continue with other foods for 12 mo.
Postpone the introduction of baby foods to 4-6 mo and juices to 12 mo.

FAMILIES
Eat meals as a family in a fixed place and time.
Do not skip meals, especially breakfast.
No television during meals.
Use small plates, and keep serving dishes away from the table.
Avoid unnecessary sweet or fatty foods and sugar-sweetened drinks.
Remove televisions from children’s bedrooms; restrict times for television viewing and video games.
Do not use food as a reward.

SCHOOLS
Eliminate candy and cookie sales as fundraisers.
Review the contents of vending machines and replace with healthier choices; eliminate sodas.
Avoid financial support for sports teams from beverage and food industries.
Install water fountains and hydration stations.
Educate teachers, especially physical education and science faculty, about basic nutrition and the benefits of physical activity.
Educate children from preschool through high school on appropriate diet and lifestyle.
Mandate minimum standards for physical education, including 60 min of strenuous exercise 5 times weekly.
Encourage “the walking school bus”: groups of children walking to school with adult supervision.

COMMUNITIES
Increase family-friendly exercise and safe play facilities for children of all ages.
Develop more mixed residential-commercial developments for walkable and bicyclable communities.
Discourage the use of elevators and moving walkways.
Provide information on how to shop and prepare healthier versions of culture-specific foods.

HEALTHCARE PROVIDERS
Explain the biologic and genetic contributions to obesity.
Give age-appropriate expectations for body weight in children.
Work toward classifying obesity as a disease to promote recognition, reimbursement for care, and willingness and ability to provide treatment.

INDUSTRY
Mandate age-appropriate nutrition labeling for products aimed at children (e.g., red light/green light foods, with portion sizes).
Encourage marketing of interactive video games in which children must exercise in order to play.
Use celebrity advertising directed at children for healthful foods to promote breakfast and regular meals.
Reduce portion size (drinks and meals).

GOVERNMENT AND REGULATORY AGENCIES
Classify childhood obesity as a legitimate disease.
Find novel ways to fund healthy lifestyle programs (e.g., with revenues from food and drink taxes).
Subsidize government-sponsored programs to promote the consumption of fresh fruits and vegetables.
Provide financial incentives to industry to develop more healthful products and to educate the consumer on product content.
Provide financial incentives to schools that initiate innovative physical activity and nutrition programs.
Allow tax deductions for the cost of weight loss and exercise programs.
Provide urban planners with funding to establish bicycle, jogging, and walking paths.
Ban advertising of fast foods, nonnutritious foods, and sugar-sweetened beverages directed at preschool children, and restrict advertising to school-age children.
Ban toys as gifts to children for purchasing fast foods.

Table 47-7  Anticipatory Guidance: Establishing Healthy Eating Habits in Children

Do not punish a child during mealtimes with regard to eating. The emotional atmosphere of a meal is very important. Interactions during meals should be pleasant and happy.
Do not use foods as rewards.
Parents, siblings, and peers should model healthy eating, tasting new foods, and eating a well-balanced meal.
Children should be exposed to a wide range of foods, tastes, and textures.
New foods should be offered multiple times. Repeated exposure leads to acceptance and liking.
Forcing a child to eat a certain food will decrease the child’s preference for that food. Children’s wariness of new foods is normal and should be expected. Offering a variety of foods with low-energy density helps children balance energy intake.
Parents should control what foods are in the home. Restricting access to foods in the home will increase rather than decrease a child’s desire for that food.
Children tend to be more aware of satiety than adults, so allow children to respond to satiety, and stop eating. Do not force children to “clean their plate.”

Bibliography

Chapter 47  Overweight and Obesity

OVERVIEW OF VITAMIN A
Vitamin A is a fat-soluble micronutrient that cannot be synthesized de novo by the mammalian body, thus it is an obligatory dietary factor. The term vitamin A is generally used to refer to a group of compounds that possess the biologic activity of all-trans retinol (Fig. 48-1). As a fat-soluble micronutrient, vitamin A is recognized as being essential for all vertebrates for normal vision, reproduction, cell and tissue differentiation, and functions of the immune system. Vitamin A plays critical roles in neonatal development. It is required for normal embryonic development, hematopoiesis, immune response, metabolism, and growth and differentiation of many types of cells.

Vitamin A can be obtained from the diet where its main form is as retinyl esters, such as retinyl palmitate, which are called preformed vitamin A. They are found primarily in certain foods of animal origin. Organ meats (especially liver, kidney) are very rich in vitamin A, while other meats, milk, and cheese contain moderate levels. Other sources of vitamin A include several provitamin A carotenoids, which are found naturally in many fruits and vegetables (pumpkin, squash, sweet potato), and leafy green vegetables (chard, spinach, broccoli). One of the most abundant carotenoids is β-carotene. α-Carotene and β-cryptoxanthin also possess vitamin A activity at a lower bioactivity. In the body, these precursors are used for the synthesis of 2 essential metabolites of vitamin A. One is all-trans retinoic acid, the form of vitamin A required for cell differentiation and the regulation of gene transcription. It is the most bioactive form of vitamin A. The other is 11-cis retinal, required for vision. It functions as the light-absorbing chromophore of the visual pigments rhodopsin and iodopsin.

Figure 48-1 Vitamin A structures (A) and overview of vitamin A metabolism (B).

METABOLISM OF VITAMIN A
Ingested retinyl esters must first be hydrolyzed in the intestinal lumen, a process that liberates unesterified retinol, for the absorption of vitamin A. Most of the retinol is then reesterified in the enterocytes. The absorption of preformed vitamin A is very efficient. Approximately 70-90% of dietary preformed vitamin A is absorbed as long as there is ~10 g or more fat in the meal. Chronic intestinal disorders or lipid malabsorption can result in vitamin A deficiency. Uncleaved provitamin-A carotenoids in the intestine are also incorporated into chylomicrons and delivered to various tissues. The estimated absorption efficiency of carotenoids is approximately 20-50%, and appears to be more variable among individuals than for preformed vitamin A. The efficiency of conversion of B-carotene to retinol is much lower than expected. The carotene cleavage enzyme β-carotene monooxygenase, present in the enterocyte, exhibits certain single nucleotide polymorphisms that reduce the efficiency of conversion of β-carotene to retinol.

Once retinol is esterified in the enterocyte, retinyl ester is then packaged into nascent chylomicrons, which are then secreted into the lymphatic vessels and transported via the circulation to the liver or to other tissues. When vitamin A status is adequate, most mammals, including humans, store most of their total body vitamin A in the liver, within stellate cells. When their vitamin A status is deficient, vitamin A stores can be mobilized; the released retinol can be used by extrahepatic tissues. Stored vitamin A is released from the liver into the circulation as retinol bound to its specific transport protein, retinol-binding protein (RBP), which binds to the thyroid hormone transport protein, transthyretin (TTR); this complex delivers retinol (as well as the thyroid hormone) to a large number of vitamin A target tissues. The major physiologic mediator of retinol uptake by cells in many tissues is Stra6, a widely expressed multitransmembrane domain protein that functions as a cell-surface receptor for retinol bound to RBP.

In target tissues, retinol is either esterified into retinyl esters for storage or oxidized into retinoic acid for function. In the eye, 11-cis-retinal is formed.

Vitamin A Status in Neonates
Neonates begin life with low levels of vitamin A, in plasma, liver, and extrahepatic tissues, compared with those in adults. Normal plasma levels of retinol are 20-50 µg/dL in infants, and increase gradually as children become older. Median serum retinol values are 1.19 µmol/L in both boys and girls ages 4-8 yr; 1.4 and 1.33 µmol/L in boys and...
Inflammation as a Cause of Low Plasma Retinol

Inflammation is a cause of reduced levels of plasma retinol as a result of reduced synthesis of RBP and TTR. This condition may mimic a lack of vitamin A, but will not be corrected by supplementation. In U.S. adults, those with moderately elevated levels of C-reactive protein, indicative of mild inflammation, had lower average plasma retinol levels. The extent to which inflammation is a factor in low plasma retinol in children is uncertain but it is likely to be significant in acute infectious diseases such as measles, and possibly in chronic inflammatory conditions such as cystic fibrosis.

FUNCTIONS OF VITAMIN A AND MECHANISMS OF ACTION

Except for its role in vision, the pleiotropic actions of this micronutrient include many systemic functions that are mediated at the gene level by all-trans-retinoic acid (RA), which is a ligand for specific nuclear transcription factors, the retinoid receptors: RARs and RXRs. When an RAR is activated by the presence of RA, it combines with an RXR, and the resulting heterodimer binds to specific DNA sequences present in retinoid responsive genes (RAREs and RXREs, respectively) and therefore induce or repress the expression of a large number of genes. In this manner, vitamin A, via its active form, RA, regulates many genes that are involved in the fundamental biologic activities of cells, such as cell division, cell death, and cell differentiation. The term retinoids includes both natural and synthetic compounds with vitamin A activity and is most often used in the context of vitamin A action at the gene level. A large number of synthetic retinoids have been produced and some have gained clinical acceptance, such as in the treatment of skin disorders and certain cancers.

Retinoic acid is among the most important signaling molecules in vertebrate ontogenesis. It affects many physiologic processes, including reproduction, growth, embryonic and fetal development, and bone development, in addition to respiratory, gastrointestinal, hematopoietic, and immune functions. The role of vitamin A in immune function and host defense is particularly important in developing countries, where vitamin A supplementation or therapy reduces the morbidity and mortality rates of various diseases, such as measles (see Chapter 246).

Vitamin A plays a critical nongenomic role in vision. The human retina has 2 distinct photoreceptor systems: the rods, containing rhodopsin, which can detect low-intensity light, and the cones, containing iodopsin, which can detect different colors. The aldehyde form of vitamin A, retinal, is the prosthetic group on both visual proteins. The mechanism of vitamin A action in vision is based on the ability of the vitamin A molecule to photoisomerize (change shape when exposed to light). Thus, in the dark, low-intensity light isomerizes the rhodopsin prosthetic group, 11-cis retinal, to all-trans-retinal, generating an electrical signal that is transmitted via the optic nerve to the brain and results in visual sensation.

VITAMIN A DEFICIENCY

If the growing child has a well-balanced diet and obtains vitamin A from foods that are rich in vitamin A or provitamin-A (Table 48-1), the risk of vitamin A deficiency is small. However, even subclinical vitamin A deficiency can have serious consequences.

Deficiency states in developed countries are rare, except in some impoverished populations (see Chapter 46) or after mistakes in food preparation or with fad diets, but they are common in many developing countries and are often associated with global malnutrition (see Chapter 46). In the clinical setting, vitamin deficiencies can also occur as complications in children with various chronic disorders or diseases. Information obtained in the medical history related to dietary habits can be important in identifying the possibility of such nutritional problems. Except for vitamin A, toxicity from excess intake of vitamins is rare. Table 48-1 summarizes the food sources, functions, and deficiency and excess symptoms of the vitamins.

Clinical Manifestations of Vitamin A Deficiency

The most obvious symptoms of vitamin A deficiency are associated with the requirement of this vitamin for the maintenance of epithelial functions. In the intestines, a normal mucus-secreting epithelium (normal goblet cell function) is an effective barrier against pathogens that can cause diarrhea. Similarly, in the respiratory tract, a mucus-secreting epithelium is essential for the disposal of inhaled pathogens and toxicants. Characteristic changes as a result of vitamin A deficiency in the epithelia include a proliferation of basal cells, hyperkeratosis, and

RAE, retinol activity equivalent.
formation of stratified cornified squamous epithelium. Squamous metaplasia of the renal pelvis, ureters, vaginal epithelium, and the pancreatic and salivary ducts can lead to increased infections in these areas. In the urinary bladder, loss of epithelial integrity can result in pyuria and hematuria. Epithelial changes in the skin caused by vitamin A deficiency are manifested as dry, scaly, hyperkeratotic patches, commonly on the arms, legs, shoulders, and buttocks. The combination of defective epithelial barriers to infection, low immune response, and lowered response to inflammatory stress, all because of insufficient vitamin A, can cause poor growth and serious health problems in children.

The most characteristic and specific signs of vitamin A deficiency are eye lesions, but they may be manifest rather late in the progression of vitamin A deficiency. Lesions caused by vitamin A deficiency develop insidiously and rarely occur before 2 yr of age. An early symptom is delayed adaptation to the dark, a result of reduced resynthesis of rhodopsin; later, when vitamin A deficiency is more advanced, it leads to night blindness as a consequence of the absence of retinal in the visual pigment, rhodopsin, of the retina. Photophobia is a common symptom. The pigment epithelium, the structural element of the retina, keratinizes. When the pigment epithelium degenerates, the rods and cones have no support and eventually break down, resulting in blindness.

As vitamin A deficiency progresses, the corneal and conjunctival epithelial tissues of the eye become severely altered; this change results from a lack of sufficient RA for normal epithelial cell morphology and function. The cornea protects the eye from the environment and is also important in light refraction. In early vitamin A deficiency, the cornea keratinizes, becomes opaque, is susceptible to infection, and forms dry, scaly layers of cells (xerophthalmia). The conjunctiva keratinizes and develops plaques (Bitot spots [Fig. 48-2]). In later stages, infection occurs, lymphocytes infiltrate, and the cornea becomes wrinkled; it degenerates irreversibly (keratomalacia and corneal ulceration), resulting in blindness. Advanced xerophthalmia (Fig. 48-3) and xerophthalmia with permanent damage to the eye (Fig. 48-4) may develop if untreated. These eye lesions are primarily diseases of the young and are a major cause of blindness in developing countries. Although rates of xerophthalmia have fallen, the number of affected children is still too high.

Other clinical signs of vitamin A deficiency include poor overall growth, diarrhea, susceptibility to infections, anemia, apathy, mental retardation, and increased intracranial pressure, with wide separation of the cranial bones at the sutures. There may be vision problems as a consequence of bone overgrowth causing pressure on the optic nerve.

Malnutrition, particularly protein deficiency, can cause vitamin A deficiency by the impaired synthesis of retinol transport protein. In developing countries, subclinical or clinical zinc deficiency can increase the risk of vitamin A deficiency. There is also some evidence of marginal zinc intakes in children in the United States.

**Diagnosis**

Dark adaptation tests can be used to assess early-stage vitamin A deficiency. Although Bitot spots develop relatively early, those related to active vitamin A deficiency are usually confined to preschool-age children. Xerophthalmia is a very characteristic lesion of vitamin A deficiency. Caution must be exercised to exclude other, similar eye abnormalities from those associated with vitamin A deficiency. There are 3 useful indicators for detecting marginal vitamin A status, although they are mostly limited to research settings: conjunctival impression cytology, relative dose response, and modified relative dose response. A diet history can also be useful in suggesting or ruling out low intake as a cause. There is a relatively high prevalence of marginal vitamin A status among pregnant and lactating women. The plasma retinol level is not an accurate indicator of vitamin A status unless the deficiency is severe and liver stores are depleted, in which case low plasma retinol is likely to be evident. In children, plasma retinol values of <0.35 µmol/L are considered to be very deficient, 0.35-0.7 µmol/L are considered to be deficient, 0.7-1.05 µmol/L are considered to be marginal, and >1.05 µmol/L are considered to be adequate. It has long been thought that the liver vitamin A concentration must be 20 µg/g or higher to support a normal rate of secretion of retinol-RBP into plasma.

**Epidemiology and Public Health Issues**

Vitamin A deficiency and xerophthalmia still occur throughout much of the developing world and are linked to undernourishment and complicated by illness. Programs to provide periodic large doses of vitamin A have been instituted in many low-income countries in which vitamin

---

A deficiency is still a public health problem. Vitamin A supplementation is considered part of the strategy of the World Health Organization’s Millennium Development Goals to reduce <5 yr mortality. Other strategies being tested include improving the content of β-carotene in staple foods through plant breeding (biofortification).

### Dietary Reference Intakes for the Healthy Population

Table 48-2 summarizes the dietary reference intakes for infants and children. Dietary reference intake values include the estimated average requirement, which is the mean biologic requirement for the nutrient in the population; the recommended dietary allowance (RDA), which is set to cover the needs of >97% of the population (thus the needs of many people are more than covered by the RDA); and the upper level (UL), an intake level above which risk of adverse effects may increase; the UL pertains only to chronic consumption of preformed vitamin A.

The RDA is expressed as retinol activity equivalents (RAEs; 1 RAE = 1 µg all-trans-retinol; equivalents for provitamin-A in foods = 12 µg β-carotene, 24 µg α-carotene, or 24 µg β-cryptoxanthin). From infancy to age 18 yr, the RDA increases as a consequence of increased body size, becoming higher for boys than girls during adolescence. During pregnancy, the RDA is 750-770 µg, and during lactation, the RDA is increased to 1,200-1,300 µg to ensure sufficient vitamin A content during breastfeeding.

It is noteworthy that, especially for young children, the UL is not far above the RDA, differing by only 2-fold in some age groups. This suggests that for children whose diet is good, care should be taken not to overuse dietary supplements containing preformed vitamin A and/or to avoid excessive consumption of foods that are rich in vitamin A, such as liver.

### Vitamin A for Treatment of Deficiency

The safety and efficacy of vitamin A supplementation depend on the patient’s state of health and the regimen of other treatments. A daily supplement of 1,500 µg of vitamin A is sufficient for treating latent vitamin A deficiency, after which intake an at RDA level should be the goal. In children without overt vitamin A deficiency, morbidity and mortality rates from viral infections, such as measles, have been reduced by administration of weekly doses equivalent to the RDA level of vitamin A, or higher doses of 30-60 mg of retinol (100,000-200,000 IU) given once or twice, under careful monitoring to avoid toxicity associated with excess vitamin A. Xerophthalmia is treated by giving 1,500 µg/kg body weight orally for 5 days followed by intramuscular injection of 7,500 µg of vitamin A in oil, until recovery.

Vitamin A is also used in preterm infants for improvement of respiratory function and prevention of the development of chronic lung disease. An analysis of 9 randomized controlled trials of vitamin A found that vitamin A appears to be beneficial in reducing death or oxygen requirement with no differences in neurodevelopmental outcomes.

### HYPERVITAMINOSIS A

Chronic hypervitaminosis A results from excessive ingestion of preformed vitamin A (retinol or retinyl ester), generally for several weeks or months. The cause is often excessive use of vitamin A-containing supplements, or food faddism resulting in excessive intakes of organ meats. Toxicity can be induced in adults and children with chronic daily intakes of 15,000 µg and 6,000 µg, respectively. As there is no antidote for hypervitaminosis A, the prevention of this condition is most important. Symptoms may subside rapidly on withdrawal of the vitamin, but the rate of improvement depends on the amount of vitamin A that has built up in tissues. In extreme cases, hypervitaminosis A can be fatal. Signs of subacute or chronic toxicity can include headache; vomiting; anorexia; dry, itchy desquamating skin; seborrheic cutaneous lesions; fissuring at the corners of the mouth; alopecia and/or coarsening of the hair; bone abnormalities; swelling of the bones; enlargement of the liver and spleen; diplopia; increased intracranial pressure; irritability; stupor; limited motion; and dryness of the mucous membranes; desquamation of the palms and the soles of the feet. Radiographs may show hyperostosis affecting several long bones, especially in the middle of the shafts (Fig. 48-5). Serum levels of vitamin

![Figure 48-5](image_url)
A are elevated, mostly as retinyl ester contained in lipoproteins, which may contribute to membrane damage and symptoms, including release of liver enzymes into plasma. Hypercalcemia and/or liver cirrhosis may be present. Hypervitaminosis A is distinct from cortical hyperostosis (see Chapter 700).

In young children, toxicity is associated with vomiting and bulging fontanels. An affected child has anorexia, pruritus, and a lack of weight gain. Acute hypervitaminosis A, such as after consumption of a single large (30-60 mg dose) of vitamin A may include nausea, vomiting, and drowsiness; less-common symptoms include diplopia, papilledema, cranial nerve palsies, and other symptoms suggesting pseudotumor cerebri.

A syndrome of severe congenital malformations may occur in infants of mothers who have consumed therapeutic doses (0.5-1.5 mg/kg) of oral 13-cis-retinoic acid (e.g., Accutane), generally taken for the treatment of acne or cancer, during the 1st trimester of pregnancy. These malformations result in a high incidence (>20%) of spontaneous abortions and birth defects including characteristic craniofacial abnormalities. The U.S. Food and Drug Administration has increased the stringency of prescription of such drugs in women of childbearing age to attempt to reduce these birth defects.

Excessive intake of carotenoids is not associated with toxicity but can cause yellow coloration of the skin (carotenodermia) and serum (carotenemia) that disappears when intake is reduced. Children with liver disease, diabetes mellitus, or hypothyroidism are more susceptible. Food faddism including an excessive consumption of carotene-rich foods may be a cause of this condition.

Chapter 48  •  Vitamin A Deficiencies and Excess  321.e1

Bibliography
Vitamin B complex includes a number of water-soluble nutrients, including thiamine (B₁), riboflavin (B₂), niacin (B₃), pyridoxine (B₆), folate, cobalamin (B₁₂), biotin, and pantothenic acid. Choline and inositol are also considered part of the B complex and are important for normal body functions, but specific deficiency syndromes have not been attributed to a lack of these factors in the diet.

B-complex vitamins serve as coenzymes in many metabolic pathways that are functionally closely related. Consequently, a lack of one of the vitamins has the potential to interrupt a chain of chemical processes, including reactions that are dependent on other vitamins, and ultimately can produce diverse clinical manifestations. Because diets deficient in any one of the B-complex vitamins are often poor sources of other B vitamins, manifestations of several vitamin B deficiencies usually can be observed in the same person. It is therefore a general practice in a patient who has evidence of deficiency of a specific B vitamin to treat with the entire B-complex group of vitamins.

**49.1 Thiamine (Vitamin B₁)**

H.P.S. Sachdev and Dheeraj Shah

Thiamine diphosphate, the active form of thiamine, serves as a cofactor for several enzymes involved in carbohydrate catabolism such as pyruvate dehydrogenase, transketolase, and α-ketoglutarate. These enzymes also play a role in the hexose monophosphate shunt that generates nicotinamide adenine dinucleotide phosphate (NADP) and pentose for nucleic acid synthesis. Thiamine is also required for the synthesis of acetylcholine and γ-aminobutyric acid, which have important roles in nerve conduction. Thiamine is absorbed efficiently in the gastrointestinal (GI) tract, and may be deficient in persons with GI or liver disease. The requirement of thiamine is increased when carbohydrates are taken in large amounts and during periods of increased metabolism, such as fever, muscular activity, hyperthyroidism, pregnancy, and lactation. Alcohol affects various aspects of thiamine transport and uptake, contributing to the deficiency in alcoholics.

Pork (especially lean), fish, and poultry are good nonvegetarian dietary sources of thiamine. Main sources of thiamine for vegetarians are rice, oat, wheat, and legumes. Most ready-to-eat breakfast cereals are enriched with thiamine. Thiamine is water soluble and heat labile; most of the vitamin is lost when the rice is repeatedly washed and the cooking water is discarded. The breast milk of a well-nourished mother provides adequate thiamine; breastfed infants of thiamine-deficient mothers are at risk for deficiency. Thiamine antagonists (coffee, tea) and thiaminases (fermented fish) may contribute to thiamine deficiency. Most infants and older children consuming a balanced diet obtain an adequate intake of thiamine from food and do not require supplements.

**DEFICIENCY**

Deficiency of thiamine is associated with severely malnourished states, including malignancy and following surgery. The disorder (or spectrum of disorders) is classically associated with a diet consisting largely of polished rice (oriental beriberi); it can also arise if highly refined wheat flour forms a major part of the diet, in alcoholics, and in food faddists (occidental beriberi). Thiamine deficiency has often been reported from inhabitants of refugee camps consuming the polished rice–based monotonous diets. Low thiamine concentrations are also noted during critical illnesses.

Thiamine-responsive megaloblastic anemia (TRMA) syndrome is a rare autosomal recessive disorder characterized by megaloblastic anemia, diabetes mellitus, and sensorineural hearing loss, responding in varying degrees to thiamine treatment. The syndrome occurs because of mutations in the SLC19A2 gene, encoding a thiamine transporter protein, leading to abnormal thiamine transportation and cellular vitamin deficiency. Thiamine and related vitamins may improve the outcome in children with Leigh encephalomyelopathy and type 1 diabetes mellitus.

**Clinical Manifestations**

Thiamine deficiency can develop within 2-3 mo of a deficient intake. Early symptoms of thiamine deficiency are nonspecific, such as fatigue, apathy, irritability, depression, drowsiness, poor mental concentration, anorexia, nausea, and abdominal discomfort. As the condition progresses, more-specific manifestations of beriberi, such as peripheral neuritis (manifesting as tingling, burning, paresthesias of the toes and feet), decreased deep tendon reflexes, loss of vibration sense, tenderness and cramping of the leg muscles, heart failure, and psychological disturbances, develop. Patients can have ptosis of the eyelids and atrophy of the optic nerve. Hoarseness or aphonia caused by paralysis of the laryngeal nerve is a characteristic sign. Muscle atrophy and tenderness of the nerve trunks are followed by ataxia, loss of coordination, and loss of deep sensation. Later signs include increased intracranial pressure, meningismus, and coma. The clinical picture of thiamine deficiency is usually divided into a dry (neuritic) type and a wet (cardiac) type. The disease is wet or dry depending on the amount of fluid that accumulates in the body as a result of factors such as cardiac and renal dysfunction, even though the exact cause for this edema is unknown. Many cases of thiamine deficiency show a mixture of both features and are more properly termed thiamine deficiency with cardiopathy and peripheral neuropathy.

The classic clinical triad of Wernicke encephalopathy (mental status changes, ocular signs, ataxia) is rarely reported in infants and
young children with severe deficiency secondary to malignancies or feeding of defective formula. An epidemic of life-threatening thiamine deficiency was seen in infants fed a defective soy-based formula that had undetectable thiamine levels. Manifestations included emesis, lethargy, restlessness, ophthalmoplegia, abdominal distention, developmental delay, failure to thrive, lactic acidosis, nystagmus, diarrhea, apnea, seizures, and auditory neuropathy.

Death from thiamine deficiency usually is secondary to cardiac involvement. The initial signs are cyanosis and dyspnea, but tachycardia, enlargement of the liver, loss of consciousness, and convulsions can develop rapidly. The heart, especially the right side, is enlarged. The electrocardiogram shows an increased Q-T interval, inverted T waves, and low voltage. These changes, as well as the cardiomegaly, rapidly revert to normal with treatment, but without prompt treatment, cardiac failure can develop rapidly and result in death. In fatal cases of beriberi, lesions are principally located in the heart, peripheral nerves, subcutaneous tissue, and serous cavities. The heart is dilated, and fatty degeneration of the myocardium is common. Generalized edema or edema of the legs, serous effusions, and venous engorgement are often present. Degeneration of myelin and axon cylinders of the peripheral nerves, with wallerian degeneration beginning in the distal locations, is also common, particularly in the lower extremities. Lesions in the brain include vascular dilation and hemorrhage.

**Diagnosis**

The diagnosis is often suspected on the basis of clinical setting and compatible symptoms. A high index of suspicion in children presenting with unexplained cardiac failure may sometimes be lifesaving. Objective biochemical tests of thiamine status include measurement of erythrocyte transketolase activity and the thiamine pyrophosphate effect. The biochemical diagnostic criteria of thiamine deficiency consist of low erythrocyte transketolase activity and high thiamine pyrophosphate effect (normal range: 0-14%). Urinary excretion of thiamine or its metabolites (thiazole or pyrimidine) after an oral loading dose of thiamine may also be measured to help identify the deficiency state. MRI changes of thiamine deficiency in infants are characterized by bilateral symmetric hyperintensities of the basal ganglia and frontal lobe, in addition to the lesions in the mamillothalamic bodies, periaqueductal region, and thalami described in adults.

**Prevention**

A maternal diet containing sufficient amounts of thiamine prevents thiamine deficiency in breastfed infants, and infant formulas marketed in all developed countries provide recommended levels of intake. During complementary feeding, adequate thiamine intake can be achieved with a varied diet that includes meat and enriched or whole-grain cereals. When the staple cereal is polished rice, special efforts need to be made to include legumes and/or nuts in the ration. Thiamine and other vitamins can be retained in rice by parboiling, a process of steaming the rice in the husk before milling. Improvement in cooking techniques, such as not discarding the water used for cooking, minimal washing of grains, and reduction of cooking time helps to minimize the thiamine losses during the preparation of food. Thiamine supplementation should be ensured during total parenteral nutrition.

**Treatment**

In the absence of GI disturbances, oral administration of thiamine is effective. Children with cardiac failure, convulsions, or coma should be given 10 mg of thiamine intramuscularly or intravenously daily for the 1st wk. This treatment should then be followed by 3-5 mg of thiamine per day orally for at least 6 wk. The response is dramatic in infants and in those having predominantly cardiovascular manifestations, whereas the neurologic response is slow and often incomplete. Epilepsy, mental disability, and language and auditory problems of varying degree have been reported in survivors of severe infantile thiamine deficiency.

Patients with beriberi often have other B-complex vitamin deficiencies; therefore, all other B-complex vitamins should also be adminis-tered. Treatment of TRMA and other dependency states require higher dosages (100-200 mg/day). The anemia responds well to thiamine administration, and insulin for associated diabetes mellitus can also be discontinued in many cases of TRMA.

**TOXICITY**

There are no reports of adverse effects from consumption of excess thiamine by ingestion of food or supplements. A few isolated cases of pruritus and anaphylaxis have been reported in patients after parenteral administration of the vitamin.

Bibliography is available at Expert Consult.

### 49.2 Riboflavin (Vitamin B₂)

**H.P.S. Sachdev and Dheeraj Shah**

Riboflavin is part of the structure of the coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide, which participate in oxidation-reduction reactions in numerous metabolic pathways and in energy production via the mitochondrial respiratory chain. Riboflavin is stable to heat, but is destroyed by light. Milk, eggs, organ meats, legumes, and mushrooms are rich dietary sources of riboflavin. Most commercial cereals, flours, and breads are enriched with riboflavin.

**DEFICIENCY**

The causes of riboflavin deficiency are mainly related to malnourished and malabsorptive states, including GI infections. Treatment with some drugs, such as probenecid, phenothiazine, or oral contraceptives, can also cause the deficiency. The side chain of the vitamin is photochemically destroyed during phototherapy for hyperbilirubinemia, as it is involved in the photosensitized oxidation of bilirubin to more polar excretable compounds. Isolated complex II deficiency, a rare mitochondrial disease manifesting in infancy and childhood, responds favorably to riboflavin supplementation and thus can be termed a dependency state. Brown-Vialetto-Van Laere syndrome (BVVLS), a rare neurologic disorder characterized by progressive neurologic deterioration, hypotonia, sensorineural hearing loss, and pontobulbar palsy responds to treatment with high doses of riboflavin. Mutations in genes coding for riboflavin transporter proteins have been identified in children with BVVLS.

**Clinical Manifestations**

Clinical features of riboflavin deficiency include cheilosis, glossitis, keratitis, conjunctivitis, photophobia, lacrimation, corneal vascularization, and seborrheic dermatitis. Cheilosis begins with pallor at the angles of the mouth and progresses to thinning and maceration of the epithelium, leading to fissures extending radially into the skin (Fig. 49-1). In glossitis, the tongue becomes smooth, with loss of papillary structure (Fig. 49-2). Normochromatic, normocytic anemia may also be seen because of the impaired erythropoiesis. A low riboflavin content of the maternal diet has been linked to congenital heart defects, but the evidence is weak.

**Diagnosis**

Most often, the diagnosis is based on the clinical features of angular cheilosis in a malnourished child, which responds promptly to riboflavin supplementation. A functional test of riboflavin status is done by measuring the activity of erythrocyte glutathione reductase (EGR), with and without the addition of FAD. An EGR activity coefficient (ratio of EGR activity with added FAD to EGR activity without FAD) of >1.4 is used as an indicator of deficiency. Urinary excretion of riboflavin <30 µg/24 hr also suggests low intakes.

**Prevention**

Table 49-1 lists the recommended daily allowance of riboflavin for infants, children, and adolescents. Adequate consumption of milk, milk products, and eggs prevents riboflavin deficiency. Fortification of

cereal products is helpful for those who follow vegan diets or who are consuming inadequate amounts of milk products for other reasons.

**Treatment**

Treatment includes oral administration of 3–10 mg/day of riboflavin, often as an ingredient of a vitamin B–complex mix. The child should also be given a well-balanced diet, including milk and milk products.

**TOXICITY**

No adverse effects associated with riboflavin intakes from food or supplements have been reported, and the upper safe limit for consumption has not been established. Although the photosensitizing property of this vitamin raises the possibility for some potential risks, limited absorption in high-intake situations precludes such concerns.

Bibliography
and steroid synthesis, cell differentiation, and DNA processing. Niacin is rapidly absorbed from the stomach and the intestines and can also be synthesized from tryptophan in the diet.

Major dietary sources of niacin are meat, fish, and poultry for non-vegetarians and cereals, legumes, and green leafy vegetables for vegetarians. Enriched and fortified cereal products and legumes also are major contributors to niacin intake. Milk and eggs contain little niacin but are good sources of tryptophan, which can be converted to nicotinamide adenine dinucleotide (60 mg tryptophan = 1 mg niacin).

DEFICIENCY

Pellagra, the classic niacin deficiency disease, occurs chiefly in populations where corn (maize), a poor source of tryptophan, is the major foodstuff. A severe dietary imbalance, such as in anorexia nervosa and in war or famine conditions, also can cause pellagra. Pellagra can also develop in conditions associated with disturbed tryptophan metabolism such as carcinoid syndrome and Hartnup disease.

Clinical Manifestations

The early symptoms of pellagra are vague: anorexia, lassitude, weakness, burning sensation, numbness, and dizziness. After a long period of deficiency, the classic triad of dermatitis, diarrhea, and dementia appears. Dermatitis, the most characteristic manifestation of pellagra, can develop suddenly or insidiously and may be initiated by irritants, including intense sunlight. The lesions first appear as symmetric areas of erythema on exposed surfaces, resembling sunburn, and might go unrecognized. The lesions are usually sharply demarcated from the surrounding healthy skin, and their distribution can change frequently. The lesions on the hands and feet often have the appearance of a glove or stocking (Fig. 49-3). Similar demarcations can also occur around the neck (Casal necklace) (Fig. 49-3). In some cases, vesicles and bullae develop (wet type). In others, there may be suppuration beneath the scaly, crusted epidermis; in still others, the swelling can disappear after a short time, followed by desquamation (Fig. 49-4). The healed parts of the skin might remain pigmented. The cutaneous lesions may be preceded by or accompanied by stomatitis, glossitis, vomiting, and/or diarrhea. Swelling and redness of the tip of the tongue and its lateral margins is often followed by intense redness, even ulceration, of the entire tongue and the papillae. Nervous symptoms include depression, disorientation, insomnia, and delirium.

The classic symptoms of pellagra usually are not well developed in infants and young children, but anorexia, irritability, anxiety, and apathy are common. Young patients might also have sore tongues and lips, and usually have dry and scaly skin. Diarrhea and constipation can alternate, and anemia can occur. Children who have pellagra often have evidence of other nutritional deficiency diseases.

Diagnosis

Because of lack of a good functional test to evaluate niacin status, the diagnosis of deficiency is usually made from the physical signs of glossitis, GI symptoms, and a symmetric dermatitis. Rapid clinical response to niacin is an important confirmatory test. A decrease in the concentration and/or a change in the proportion of the niacin metabolites N'-methyl-nicotinamide and 2-pyridone in the urine provide biochemical evidence of deficiency and can be seen before the appearance of overt signs of deficiency. Histopathologic changes from the affected skin include dilated blood vessels without significant inflammatory infiltrates, ballooning of the keratinocytes, hyperkeratosis, and epidermal necrosis.

Prevention

Adequate intakes of niacin are easily met by consumption of a diet that consists of a variety of foods and includes meat, eggs, milk, and enriched or fortified cereal products. The dietary reference intake (DRI) is expressed in mg niacin equivalents (NE) in which 1 mg NE = 1 mg niacin or 60 mg tryptophan. An intake of 2 mg of niacin is considered adequate for infants 0-6 mo of age; and 4 mg is adequate for infants 7-12 mo of age. For older children, the recommended...
intakes are 6 mg for 1-3 yr of age, 8 mg for 4-8 yr of age, 12 mg for 9-13 yr of age, and 14-16 mg for 14-18 yr of age.

**Treatment**

Children usually respond rapidly to treatment. A liberal and varied diet should be supplemented with 50-300 mg/day of niacin; in severe cases or in patients with poor intestinal absorption, 100 mg may be given intravenously. The diet should also be supplemented with other vitamins, especially other B-complex vitamins. Sun exposure should be avoided during the active phase of pellagra, and the skin lesions may be covered with soothing applications. Other coexisting nutrient deficiencies such as iron deficiency anemia should be treated. Even after successful treatment, the diet should continue to be monitored to prevent recurrence.

**TOXICITY**

There are no toxic effects associated with the intake of naturally occurring niacin in foods. Shortly after the ingestion of large doses of nictinic acid taken as a supplement or a pharmacologic agent, a person often experiences a burning, tingling, and itching sensation as well as flushing on the face, arms, and chest. Large doses of niacin also can have nonspecific GI effects and can cause cholestatic jaundice or hepatoxicity. Tolerable upper intake levels for children are approximately double the recommended dietary allowance.

*Bibliography is available at Expert Consult.*

### 49.4 Vitamin B₆ (Pyridoxine)

**H.P.S. Sachdev and Dheeraj Shah**

Vitamin B₆ includes a group of closely related compounds: pyridoxine, pyridoxal, pyridoxamine, and their phosphorylated derivatives. Pyridoxal 5’-phosphate (PLP) and, to a lesser extent, pyridoxamine phosphate function as coenzymes for many enzymes involved in amino acid metabolism, neurotransmitter synthesis, glycogen metabolism, and steroid action. If vitamin B₆ is lacking, glycine metabolism can lead to oxaluria. The major excretory product in the urine is 4-pyridoxic acid.

The vitamin B₆ content of human milk and infant formulas is adequate. Good food sources of the vitamin include fortified ready-to-eat cereals, meat, fish, poultry, liver, bananas, rice, and certain vegetables. Large losses of the vitamin can occur during high-temperature processing of foods or milling of cereals, whereas parboiling of rice prevents its loss.

**DEFICIENCY**

Because of the importance of vitamin B₆ in amino acid metabolism, high protein intakes can increase the requirement for the vitamin; the recommended daily allowances are sufficient to cover the expected range of protein intake in the population. The risk of deficiency is increased in persons taking medications that inhibit the activity of vitamin B₆ (isoniazid, penicillamine, corticosteroids, phenytoin, carbamazepine), in young women taking oral progesterone-estrogen contraceptives, and in patients receiving maintenance dialysis.

**Clinical Manifestations**

The deficiency symptoms seen in infants are listlessness, irritability, seizures, vomiting, and failure to thrive. Peripheral neuritis is a feature of deficiency in adults but is not usually seen in children. Electroencephalogram (EEG) abnormalities have been reported in infants as well as in young adult subjects in controlled depletion studies. Skin lesions include cheilosis, glossitis, and seborrheic dermatitis around the eyes, nose, and mouth. Microcytic anemia can occur in infants, but is not common. Oxaluria, oxalic acid bladder stones, hyperglycinemia, lymphopenia, decreased antibody formation, and infections also are associated with vitamin B₆ deficiency.

Several types of vitamin B₆ dependence syndromes, presumably resulting from errors in enzyme structure or function, respond to very large amounts of pyridoxine. These syndromes include pyridoxine-dependent epilepsy, a vitamin B₆–responsive anemia, xanthurenic aciduria, cystathioninuria, and homocystinuria (see Chapters 85, 456, and 601). Pyridoxine-dependent epilepsy involves mutations in the ALDH7A1 gene causing deficiency of antiquitin, an enzyme involved in dehydrogenation of 1-alpha-aminoadipic semialdehyde.

**Diagnosis**

The activity of the erythrocyte transaminases glutamic oxaloacetic transaminase and glutamic pyruvic transaminase is low in vitamin B₆ deficiency; tests measuring the activity of these enzymes before and after the addition of PLP may be useful as indicators of vitamin B₆ status. Abnormally high xanthurenic acid excretion after tryptophan ingestion also provides evidence of deficiency. Plasma PLP assays are being used more often, but factors other than deficiency can influence the results. Vitamin B₆ deficiency or dependence should be suspected in all infants with seizures. If more common causes of infantile seizures have been eliminated, 100 mg of pyridoxine can be injected, with EEG monitoring if possible. If the seizure stops, vitamin B₆ deficiency should be suspected. In older children, 100 mg of pyridoxine may be injected intramuscularly while the EEG is being recorded; a favorable response of the EEG suggests pyridoxine deficiency.

**Prevention**

Deficiency is unlikely in children consuming diets that meet their energy needs and contain a variety of foods. Parboiling of rice prevents the loss of vitamin B₆ from the grains. The DRIs for vitamin B₆ are 0.1 mg/day for infants up to 6 mo of age; 0.3 mg/day for ages 6 mo to 1 yr; 0.5 mg/day for ages 1-3 yr; 0.6 mg/day for ages 4-8 yr; 1.0 mg/day for ages 9-13 yr; and 1.2-1.3 mg/day for ages 14-18 yr. Infants whose mothers have received large doses of pyridoxine during pregnancy are at increased risk for seizures from pyridoxine dependence, and supplements during the 1st few weeks of life should be considered. Any child receiving a pyridoxine antagonist, such as isoniazid, should be carefully observed for neurologic manifestations; if these develop, vitamin B₆ should be administered or the dose of the antagonist should be decreased.

**Treatment**

Intramuscular or intravenous administration of 100 mg of pyridoxine is used to treat convulsions caused by vitamin B₆ deficiency. One dose should be sufficient if adequate dietary intake follows. For pyridoxine-dependent children, daily doses of 2-10 mg intramuscularly or 10-100 mg orally may be necessary.

**TOXICITY**

Adverse effects have not been associated with high intakes of vitamin B₆ from food sources. However, ataxia and sensory neuropathy have been reported with dosages as low as 100 mg/day in adults taking vitamin B₆ supplements for several months.

*Bibliography is available at Expert Consult.*

### 49.5 Biotin

**H.P.S. Sachdev and Dheeraj Shah**

Biotin functions as a cofactor for enzymes involved in carboxylation reactions within and outside mitochondria. These biotin-dependent carboxylases catalyze key reactions in gluconeogenesis, fatty acid metabolism, and amino acid catabolism. There is limited information on the biotin content of foods; it is believed to be widely distributed, thus making a deficiency unlikely. Avidin found in raw egg whites acts as a biotin antagonist. Signs of biotin deficiency have been demonstrated in persons who consume large amounts of raw egg whites over long periods. Deficiency also has been described in infants and children receiving enteral and parenteral
Bibliography

Bibliography

The adequate dietary intake values for biotin are 5 µg/day for ages 0-6 mo, 6 µg/day for ages 7-12 mo, 8 µg/day for ages 1-3 yr, 12 µg/day for ages 4-8 yr, 20 µg/day for ages 9-13 yr, and 25 µg/day for ages 14-18 yr. No toxic effects have been reported with very high doses.

Bibliography is available at Expert Consult.

49.6 Folate

H.P.S. Sachdev and Dheeraj Shah

Folate exists in a number of different chemical forms. Folic acid (pteroylglutamic acid) is the synthetic form used in fortified foods and supplements. Naturally occurring folates in foods retain the core chemical structure of pteroylglutamic acid but vary in their state of reduction, the single carbon moiety they bear, or the length of the glutamate chain. These polyglutamates are broken down and reduced in the small intestine to dihydro- and tetrahydrofolates, which are involved as coenzymes in amino acid and nucleotide metabolism as acceptors and donors of 1-carbon units. Folate is important for central nervous system development during embryogenesis.

Rice and cereals are rich dietary sources of folate, especially if enriched. Beans, leafy vegetables, and fruits such as oranges and papaya are good sources, too. The vitamin is readily absorbed from the small intestine and is broken down to monoglutamate derivatives by mucosal polyglutamate hydrolases. A high-affinity proton-coupled folate transporter (PCFT) seems to be essential for absorption of folate in intestine and in various cell types at low pH. The vitamin is also synthesized by the colonic bacteria, and the half-life of the vitamin is prolonged by enterohepatic recirculation.

DEFICIENCY

Because of its role in protein, DNA, and RNA synthesis, the risk of deficiency is increased during periods of rapid growth or increased cellular metabolism. Folate deficiency can result from poor nutrient content in diet, inadequate absorption (celiac disease, inflammatory bowel disease), increased requirement (sickle cell anemia, psoriasis, malignancies, periods of rapid growth as in infancy and adolescence), or inadequate utilization (long-term treatment with high-dose nonsteroidal antiinflammatory drugs; anticonvulsants such as phenytoin and phenobarbital; and methotrexate). Rare causes of deficiency are hereditary folate malabsorption, inborn errors of folate metabolism (methylene tetrahydrofolate reductase, methionine synthase reductase, and glutamate formiminotransferase deficiencies), and cerebral folate deficiency. A loss-of-function mutation in the gene coding for PCFT is the molecular basis for hereditary folate malabsorption. A high-affinity blocking autoantibody against the membrane-bound folate receptor in the choroid plexus preventing its transport across the blood–brain barrier is the likely cause of the infantile cerebral folate deficiency.

Clinical Manifestations

Folic acid deficiency results in megaloblastic anemia and hypersegmentation of neutrophils. Nonhematologic manifestations include glossitis, listlessness, and growth retardation not related to anemia. There is an association between low maternal folic acid status and neural tube defects, primarily spina bifida and anencephaly, and the role of periconceptional folic acid in their prevention is well established.

Hereditary folate malabsorption manifests at 1-3 mo of age with recurrent or chronic diarrhea, failure to thrive, oral ulcerations, neurologic deterioration, megaloblastic anemia, and opportunistic infections. Cerebral folate deficiency manifests at 4-6 mo of age with irritability, microcephaly, developmental delay, cerebellar ataxia, pyramidal tract signs, choreoathetosis, ballismus, seizures, and blindness as a result of optic atrophy. 5-Methyltetrahydrofolate levels are normal in serum and red blood cells (RBCs), but are markedly depressed in the cerebrospinal fluid.
Bibliography

Vitamin B<sub>12</sub>, in the form of deoxyadenosylcobalamin, functions as a cofactor for isomerization of methylmalonyl-CoA to succinyl-CoA, an essential reaction in lipid and carbohydrate metabolism. Methylcobalamin is another circulating form of vitamin B<sub>12</sub>, and is essential for methyl group transfer during the conversion of homocysteine to methionine. This reaction also requires a folic acid cofactor and is important for protein and nucleic acid biosynthesis. Vitamin B<sub>12</sub> is important for hematopoiesis, central nervous system myelination, and mental and psychomotor development.

**Dietary sources** of vitamin B<sub>12</sub> are almost exclusively from animal foods. Organ meats, muscle meats, sea foods (mollusks, oysters, fish), poultry, and egg yolk are rich sources. Fortified ready-to-eat cereals and milk and their products are the important sources of the vitamin for vegetarians. Human milk is an adequate source for breastfeeding infants if the maternal serum B<sub>12</sub> levels are adequate. The vitamin is absorbed from ileum at alkaline pH after binding with intrinsic factor. Enterohepatic circulation, direct absorption, and synthesis by intestinal bacteria are additional mechanisms helping to maintain the vitamin B<sub>12</sub> nutriture.

**Deficiency**

Vitamin B<sub>12</sub> deficiency because of inadequate dietary intake occurs primarily in persons consuming strict vegetarian or vegan diets. Prevalence of vitamin B<sub>12</sub> deficiency is high in predominantly vegetarian or lactovegetarian populations. Breastfeeding infants of B<sub>12</sub>-deficient mothers are also at risk for significant deficiency. Malabsorption of B<sub>12</sub> occurs in celiac disease, ileal resections, Crohn disease, *Helicobacter pylori* infection, and autoimmune atrophic gastritis (pernicious anemia). Use of proton pump inhibitors and/or histamine 2 receptor antagonists may increase the risk of deficiency. Hereditary intrinsic factor deficiency and Imerslund-Gräsbeck disease are inborn errors of metabolism leading to vitamin B<sub>12</sub> malabsorption. Mutations in the hereditary intrinsic factor gene cause hereditary intrinsic factor deficiency, whereas mutations in any of the 2 subunits (cubulin and amnionless) of the intrinsic factor receptor cause Imerslund-Gräsbeck disease.

**Clinical Manifestations**

The hematologic manifestations of vitamin B<sub>12</sub> deficiency are similar to manifestations of folate deficiency and are discussed in Chapter 454.2. Irritability, hypotonia, developmental delay, developmental regression, and involuntary movements are the common neurologic symptoms in infants and children, whereas sensory deficits, paresthesias, and peripheral neuritis are seen in adults. Hyperpigmentation of the knuckles (Fig. 49-6) and palms is another common observation with B<sub>12</sub> deficiency in children. Maternal B<sub>12</sub> deficiency may also be an independent risk factor for fetal neural tube defects.
Bibliography

**Diagnosis**
See Chapter 454.2.

**Treatment**
The hematologic symptoms respond promptly to parenteral administration of 250-1,000 µg vitamin B₁₂. Children with severe deficiency and those with neurologic symptoms need repeated doses; daily or alternate days in first week followed by weekly for the first 1-2 mo, and then monthly thereafter. Children having only hematologic presentation recover fully within 2-3 mo, whereas those with neurologic disease need at least 6 mo of therapy. Children with continuing malabsorptive state, and those having inborn errors of vitamin B₁₂ malabsorption need lifelong treatment. Prolonged daily treatment with high dose (1,000-2,000 µg) oral vitamin B₁₂ preparations has also been found to be equally effective in achieving hematologic and neurologic responses in the elderly, but the data are inadequate in children and young adults.

**Prevention**
The DRIs are 0.4 µg/day at age 0-6 mo, 0.5 µg/day at age 6-12 mo, 0.9 µg/day at age 1-3 yr, 1.2 µg/day at age 4-8 yr, 1.8 µg/day at age 9-13 yr, 2.4 µg/day at age 14-18 yr and in adults, 2.6 µg/day in pregnancy, and 2.8 µg/day in lactation. Pregnant and breastfeeding women should ensure an adequate consumption of animal products to prevent the deficiency in infants. Strict vegetarians, especially vegans, should ensure regular consumption of vitamin B₁₂. Food fortification with the vitamin helps to prevent deficiency in predominantly vegetarian populations.

Bibliography
Chapter 50  •  Vitamin C (Ascorbic Acid)  329

Chapter 50  
Vitamin C (Ascorbic Acid)  
Dheeraj Shah and H.P.S. Sachdev

Absorption of vitamin C occurs in the upper small intestine by an active process or by simple diffusion when large amounts are ingested. Vitamin C is not stored in the body but is taken up by all tissues; the highest levels are found in the pituitary and adrenal glands. The brain ascorbate content in the fetus and neonate is manyfold higher than the content in the adult brain, a finding probably related to its function in neurotransmitter synthesis.

When a mother’s intake of vitamin C during pregnancy and lactation is adequate, the newborn will have adequate tissue levels of vitamin C related to active placental transfer, subsequently maintained by the vitamin C in breast milk or commercial infant formulas. Breast milk contains sufficient vitamin C to prevent deficiency throughout infancy. Infants consuming pasteurized or boiled animal milk are at significant risk of developing deficiency if the other sources of vitamin C are also lacking in the diet. Neonates whose feeding has been delayed because of clinical condition can also suffer from ascorbic acid deficiency. For patients on total parenteral nutrition, a parenteral dose of 80 mg/day is recommended for full-term infants and a parenteral dose of 25 mg/kg/day is recommended for preterm infants. Children who choose a limited diet or those on fad diets are at risk for vitamin C deficiency.

DEFICIENCY

A deficiency of vitamin C results in the clinical presentation of scurvy, the oldest nutritional deficiency disease to be recognized. Children fed predominantly heat-treated (ultrahigh-temperature or pasteurized) milk or unfortified formulas and not receiving fruits and fruit juices are at significant risk for symptomatic disease. In scurvy, there is defective formation of connective tissues and collagen in skin, cartilage, dentine, bone, and blood vessels, leading to their fragility. In the long bones, osteoid is not deposited by osteoblasts, cortex is thin, and the trabeculae become brittle and fracture easily.

Clinical Features

The early manifestations are irritability, loss of appetite, low-grade fever, musculoskeletal pain, and tenderness in the legs. These signs and symptoms are followed by leg swelling—most marked at the knees and the ankles—and pseudoparalysis. The infant might lie with the hips and knees semiflexed and the feet rotated outward. Subperiosteal hemorrhages in the lower limb bones sometimes acutely increase the swelling and pain, and the condition might mimic acute osteomyelitis or arthritis. A "rosary" at the costochondral junctions and depression of the sternum are other typical features (Fig. 50-1). The angulation of scurbotic beads is usually sharper than the angulation of a rachitic rosary. Gum changes are seen in older children after teeth have erupted and are manifested as bluish purple, spongy swellings of the mucous membrane, especially over the upper incisors (Fig. 50-2). Anemia, a common finding in infants and young children with scurvy, is related to impaired iron absorption and coexistent hematopoietic nutrient deficiencies including iron, vitamin B₁₂, and folate. Hemorrhagic
manifestations of scurvy include petechiae, purpura, and ecchymoses at pressure points; epistaxis; gum bleeding; and the characteristic perifollicular hemorrhages (Fig. 50-3). Other manifestations are poor wound and fracture healing, hyperkeratosis of hair follicles, arthralgia, and muscle weakness.

**Laboratory Findings and Diagnosis**

The diagnosis of vitamin C deficiency is usually based on the characteristic clinical picture, the radiographic appearance of the long bones, and a history of poor vitamin C intake. The typical radiographic changes occur at the distal ends of the long bones and are particularly common at the knees. The shafts of the long bones have a ground-glass appearance because of trabecular atrophy. The cortex is thin and dense, giving the appearance of pencil outlining of the diaphysis and epiphysis. The white line of Fränkel, an irregular but thickened white line at the metaphysis, represents the zone of well-calcified cartilage. The epiphyseal centers of ossification also have a ground-glass appearance and are surrounded by a sclerotic ring (Fig. 50-4). The more specific but late radiologic feature of scurvy is a zone of rarefaction under the white line at the metaphysis. This zone of rarefaction (Trümmerfeld zone), a linear break in the bone that is proximal and parallel to the white line, represents area of debris of broken-down bone trabeculae and connective tissue. A Pelkan spur is a lateral prolongation of the white line and may be present at cortical ends. Epiphyseal separation can occur along the line of destruction, with either linear displacement or compression of the epiphysis against the shaft (Fig. 50-5). Subperiosteal hemorrhages are not visible using plain radiographs during the active phase of scurvy. However, during healing the elevated periosteum becomes calcified and radiopaque (Fig. 50-5), sometimes giving a dumbbell or club shape to the affected bone. MRI can demonstrate acute as well as healing subperiosteal hematomas along with periostitis, metaphyseal changes, and heterogeneous bone marrow signal intensity, even in absence of changes in plain radiographs. Gelatinous transformation of bone marrow, on aspiration, has been reported in children where the procedure was done on suspicion of a malignancy.

Biochemical tests are not very useful in the diagnosis of scurvy, because they do not reflect the tissue status. A plasma ascorbate concentration of <0.2 mg/dL usually is considered deficient. Leukocyte concentration of vitamin C is a better indicator of body stores, but this measurement is technically more difficult to perform. Leukocyte concentrations of ≤10 µg/10⁸ white blood cells are considered deficient and indicate latent scurvy, even in the absence of clinical signs of deficiency. Saturation of the tissues with vitamin C can be estimated from the urinary excretion of the vitamin after a test dose of ascorbic acid. In healthy children, 80% of the test dose appears in the urine within 3-5 hr after parenteral administration. Generalized nonspecific aminoaciduria is common in scurvy, whereas plasma amino acid levels remain normal.

**Differential Diagnosis**

Scurvy is often misdiagnosed as arthritis, osteomyelitis, nonaccidental trauma (child abuse), or acrodynia. The early irritability and bone pain are sometimes attributed to nonspecific pains or other nutritional deficiencies. Copper deficiency results in a radiographic picture very
similar to that of scurvy. Henoch-Schönlein purpura, thrombocytopenic purpura, or leukemia is sometimes suspected in children presenting with hemorrhagic manifestations.

**Treatment**
Vitamin C supplements of 100-200 mg/day orally or parenterally ensure rapid and complete cure. The clinical improvement is seen within a week in most cases, but the treatment should be continued for up to 3 mo for complete recovery.

**Prevention**
Breastfeeding protects against vitamin C deficiency throughout infancy. In children consuming milk formula, fortification with vitamin C must be ensured. Children consuming heat-treated milk should consume adequate vitamin C–rich foods in infancy. Dietary or medicinal supplements are required in severely malnourished children, and chronic debilitating conditions such as malignancies and neurologic disorders.

**TOXICITY**
Daily intake of <2 g of vitamin C is generally without adverse effects in adults. Larger doses can cause gastrointestinal problems, such as abdominal pain and osmotic diarrhea. Megadoses of vitamin C should be avoided in patients with a history of urolithiasis or conditions related to excessive iron accumulation such as thalassemia and hemochromatosis. There is a paucity of data regarding vitamin C toxicity in children. The following values for tolerable upper intake levels are extrapolated from data for adults based on body weight differences: age 1-3 yr, 400 mg; age 4-8 yr, 650 mg; age 9-13 yr, 1,200 mg; and age 14-18 yr, 1,800 mg.

RICKETS

Bone consists of a protein matrix called osteoid and a mineral phase, principally composed of calcium and phosphate, mostly in the form of hydroxyapatite. Osteomalacia is present when there is inadequate mineralization of bone osteoid and occurs in children and adults. Rickets is a disease of growing bone that is caused by unmineralized matrix at the growth plates and occurs in children only before fusion of the epiphyses. Because growth plate cartilage and osteoid continue to expand but mineralization is inadequate, the growth plate thickens. There is also an increase in the circumference of the growth plate and the metaphysis, increasing bone width at the location of the growth plates and causing some of the classic clinical manifestations, such as widening of the wrists and ankles. There is a general softening of the bones that causes them to bend easily when subject to forces such as weight bearing or muscle pull. This softening leads to a variety of bone deformities.

Rickets is principally caused by vitamin D deficiency (Table 51-1) and was rampant in northern Europe and the United States during the early years of the 20th century. Although this problem was largely corrected through public health measures that provided children with adequate vitamin D, rickets remains a persistent problem in developed countries, with many cases still secondary to preventable nutritional vitamin D deficiency. It remains a significant problem in developing countries, and may be secondary to nutritional vitamin D deficiency and inadequate intake of calcium.

Etiology

There are many causes of rickets (Table 51-2), including vitamin D disorders, calcium deficiency, phosphorous deficiency, and distal renal tubular acidosis.

Clinical Manifestations

Most manifestations of rickets are a result of skeletal changes (Table 51-3). Craniotabes is a softening of the cranial bones and can be detected by applying pressure at the occiput or over the parietal bones. The sensation is similar to the feel of pressing into a ping-pong ball and then releasing. Craniotabes may also be secondary to osteogenesis imperfecta, hydrocephalus, and syphilis. It is a normal finding in many newborns, especially near the suture lines, but it typically disappears within a few months of birth. Widening of the costochondral junctions results in a rachitic rosary, which feels like the beads of a rosary as the examiner’s fingers move along the costochondral junctions from rib to rib (Fig. 51-1). Growth plate widening is also responsible for the enlargement at the wrists and ankles. The horizontal depression along the lower anterior chest known as Harrison groove occurs from pulling of the softened ribs by the diaphragm during inspiration (Fig. 51-2). Softening of the ribs also impairs air movement and predisposes patients to atelectasis and pneumonia.

There is some variation in the clinical presentation of rickets based on the etiology. Changes in the lower extremities tend to be the dominant feature in X-linked hypophosphatemic rickets. Symptoms secondary to hypocalcemia occur only in those forms of rickets associated with decreased serum calcium (Table 51-4).

The chief complaint in a child with rickets is quite variable. Many children present because of skeletal deformities, whereas others have difficulty walking owing to a combination of deformity and weakness. Other common presenting complaints include failure to thrive and symptomatic hypocalcemia (see Chapter 572).

| HYPOCALCEMIC SYMPTOMS† | Tetany | Seizures | Stridor due to laryngeal spasm |

*Disorders secondary to excess fibroblast growth factor-23.
†These features are most commonly associated with the vitamin D–deficiency disorders.
‡These symptoms develop only in children with disorders that produce hypocalcemia (see Table 51-4).
Radiology
Rachitic changes are most easily visualized on posteroanterior radiographs of the wrist, although characteristic rachitic changes can be seen at other growth plates (Figs. 51-3 and 51-4). Decreased calcification leads to thickening of the growth plate. The edge of the metaphysis loses its sharp border, which is described as fraying. The edge of the metaphysis changes from a convex or flat surface to a more concave surface. This change to a concave surface is termed cupping and is most easily seen at the distal ends of the radius, ulna, and fibula. There is widening of the distal end of the metaphysis, corresponding to the clinical observation of thickened wrists and ankles, as well as the rachitic rosary. Other radiologic features include coarse trabeculation of the diaphysis and generalized rarefaction.

Diagnosis
Most cases of rickets are diagnosed based on the presence of classic radiographic abnormalities. The diagnosis is supported by physical examination findings (see Table 51-3) and a history and laboratory test results that are consistent with a specific etiology.

Clinical Evaluation
Because the majority of children with rickets have a nutritional deficiency, the initial evaluation should focus on a dietary history, emphasizing intake of vitamin D and calcium. Most children in industrialized nations receive vitamin D from formula, fortified milk, or vitamin supplements. Along with the amount, the exact composition of the formula or milk is pertinent, because rickets has occurred in children given products that are called milk (e.g., soy milk) but are deficient in vitamin D and/or minerals.

Cutaneous synthesis mediated by sunlight exposure is an important source of vitamin D. It is important to ask about time spent outside, sunscreen use, and clothing, especially if there may be a cultural reason for increased covering of the skin. Because winter sunlight is ineffective at stimulating cutaneous synthesis of vitamin D, the season is an additional consideration. Children with increased skin pigmentation are at increased risk for vitamin D deficiency because of decreased cutaneous synthesis.

The presence of maternal risk factors for nutritional vitamin D deficiency, including diet and sun exposure, is an important consideration when a neonate or young infant has rachitic findings, especially if the infant is breastfed. Determining a child's intake of dairy products, the main dietary source of calcium, provides a general sense of calcium intake. High dietary fiber can interfere with calcium absorption.

The child's medication use is relevant, because certain medications, such as the anticonvulsants phenobarbital and phenytoin, increase degradation of vitamin D, and aluminum-containing antacids interfere with the absorption of phosphate.

Malabsorption of vitamin D is suggested by a history of liver or intestinal disease. Undiagnosed liver or intestinal disease should be suspected if the child has gastrointestinal (GI) symptoms, although occasionally rickets is the presenting complaint. Fat malabsorption is
often associated with diarrhea or oily stools, and there may be signs or symptoms suggesting deficiencies of other fat-soluble vitamins (A, E, and K; see Chapters 48, 52, and 53).

A history of renal disease (proteinuria, hematuria, urinary tract infections) is an additional significant consideration, given the importance of chronic kidney disease as a cause of rickets. Polyuria can occur in children with chronic kidney disease or Fanconi syndrome.

Children with rickets might have a history of dental caries, poor growth, delayed walking, waddling gait, pneumonia, and hypocalcemic symptoms.

The family history is critical, given the large number of genetic causes of rickets, although most of these causes are rare. Along with bone disease, it is important to inquire about leg deformities, difficulties with walking, or unexplained short stature, because some parents may be unaware of their diagnosis. Undiagnosed disease in the mother is not unusual in X-linked hypophosphatemia. A history of a unexplained sibling death during infancy may be present in the child with cystinosis, the most common cause of Fanconi syndrome in children.

The physical examination focuses on detecting manifestations of rickets (see Table 51-3). It is important to observe the child’s gait, auscultate the lungs to detect atelectasis or pneumonia, and plot the patient’s growth. Alopecia suggests vitamin D–dependent rickets type 2.

The initial laboratory tests in a child with rickets should include serum calcium, phosphorus, alkaline phosphatase, parathyroid hormone (PTH), 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D, creatinine, and electrolytes (see Tables 51-4 and 51-5 for interpretation). Urinalysis is useful for detecting the glycosuria and aminoaciduria (positive dipstick for protein) seen with Fanconi syndrome. Evaluation of urinary excretion of calcium (24 hr collection for calcium or calcium: creatinine ratio) is helpful if hereditary hypophosphatemic rickets with hypercalciuria or Fanconi syndrome is suspected. Direct measurement of other fat-soluble vitamins (A, E, and

K) or indirect assessment of deficiency (prothrombin time for vitamin D deficiency) is appropriate if malabsorption is a consideration.

**VITAMIN D DISORDERS**

**Vitamin D Physiology**

Vitamin D can be synthesized in skin epithelial cells and therefore technically is not a vitamin. Cutaneous synthesis is normally the most important source of vitamin D and depends on the conversion of 7-dehydrocholesterol to vitamin D₃ (3-cholecalciferol) by ultraviolet B radiation from the sun. The efficiency of this process is decreased by melanin; hence, more sun exposure is necessary for vitamin D synthesis in people with increased skin pigmentation. Measures to decrease sun exposure, such as covering the skin with clothing or applying sunscreen, also decrease vitamin D synthesis. Children who spend less time outside have reduced vitamin D synthesis. The winter sun away from the equator is ineffective at mediating vitamin D synthesis.

There are few natural dietary sources of vitamin D. Fish liver oils have a high vitamin D content. Other good dietary sources include fatty fish and egg yolks. Most children in industrialized countries receive vitamin D via fortified foods, especially formula and milk (both of which contain 400 IU/L) and some breakfast cereals and breads. Supplemental vitamin D may be vitamin D₃ (which comes from plants or yeast) or vitamin D₂. Breast milk has a low vitamin D content, approximately 12-60 IU/L.

Vitamin D is transported bound to vitamin D-binding protein to the liver, where 25-hydroxylase converts vitamin D into 25-hydroxyvitamin D (25-(D)), the most abundant circulating form of vitamin D. Because there is little regulation of this liver hydroxylase step, measurement of 25-D is the standard method for determining a patient’s vitamin D status. The final step in activation occurs in the kidney, where 1α-hydroxylase adds a second hydroxyl group, resulting in 1,25-D. The 1α-hydroxylase is upregulated by PTH and hypophosphatemia; hyperphosphatemia and 1,25-D inhibit this enzyme. Most 1,25-D circulates bound to vitamin D-binding protein.

1,25-D acts by binding to an intracellular receptor, and the complex affects gene expression by interacting with vitamin D-responsive elements. In the intestine, this binding results in a marked increase in calcium absorption, which is highly dependent on 1,25-D. There is also an increase in phosphorus absorption, but this effect is less significant because most dietary phosphorus absorption is vitamin D independent. 1,25-D also has direct effects on bone, including mediating resorption. 1,25-D directly suppresses PTH secretion by the parathyroid gland, thus completing a negative feedback loop. PTH secretion is also suppressed by the increase in serum calcium mediated by 1,25-D. 1,25-D inhibits its own synthesis in the kidney and increases the synthesis of inactive metabolites.

**Nutritional Vitamin D Deficiency**

Vitamin D deficiency remains the most common cause of rickets globally and is prevalent, even in industrialized countries. Because vitamin D can be obtained from dietary sources or from cutaneous synthesis, most patients in industrialized countries have a combination of risk factors that lead to vitamin D deficiency.

**Etiology**

Vitamin D deficiency most commonly occurs in infancy because of a combination of poor intake and inadequate cutaneous synthesis. Transplacental transport of vitamin D, mostly 25-D, typically provides enough vitamin D for the 1st 2 mo of life unless there is severe maternal vitamin D deficiency. Infants who receive formula receive adequate vitamin D, even without cutaneous synthesis. Because of the low vitamin D content of breast milk, breastfed infants rely on cutaneous synthesis or vitamin supplements. Cutaneous synthesis can be limited because of the ineffectiveness of the winter sun in stimulating vitamin D synthesis; avoidance of sunlight because of concerns about cancer, neighborhood safety, or cultural practices; and decreased cutaneous synthesis because of increased skin pigmentation.

The effect of skin pigmentation explains why most cases of nutritional rickets in the United States and northern Europe occur in breastfed children of African descent or other dark-pigmented populations. The additional impact of the winter sun is supported by the fact that such infants more commonly present in the late winter or spring. In some groups, complete covering of infants or the practice of not taking infants outside has a significant role, explaining the occurrence of rickets in infants living in areas of abundant sunshine, such as the Middle East. Because the mothers of some infants can have the same risk factors, decreased maternal vitamin D can also contribute, both by leading to reduced vitamin D content in breast milk and by lessening transplacental delivery of vitamin D. Rickets caused by vitamin D deficiency can also be secondary to unconventional dietary practices, such as vegan diets that use unfortified soy milk or rice milk.

**Clinical Manifestations**

The clinical features are typical of rickets (see Table 51-3), with a significant minority presenting with symptoms of hypocalcemia; prolonged laryngospasm is occasionally fatal. These children have an increased risk of pneumonia and muscle weakness leading to a delay in motor development.

**Laboratory Findings**

Tables 51-4 and 51-5 summarize the principal laboratory findings. Hypocalcemia is a variable finding as a result of the actions of the elevated PTH to increase the serum calcium concentration. The hypophosphatemia is caused by PTH-induced renal losses of phosphate, combined with a decrease in intestinal absorption.

The wide variation in 1,25-D levels (low, normal, or high) is secondary to the upregulation of renal 1α-hydroxylase caused by concurrent hypophosphatemia and hyperparathyroidism. Because serum levels of 1,25-D are much lower than the levels of 25-D, even with low levels of 25-D there is still often enough 25-D present to act as a precursor for 1,25-D synthesis in the presence of an upregulated 1α-hydroxylase. The level of 1,25-D is only low when there is severe vitamin D deficiency.

Some patients have a metabolic acidosis secondary to PTH-induced renal bicarbonate wasting. There may also be generalized aminoaciduria.

**Diagnosis and Differential Diagnosis**

The diagnosis of nutritional vitamin D deficiency is based on the combination of a history of poor vitamin D intake and risk factors for decreased cutaneous synthesis, radiographic changes consistent with rickets, and typical laboratory findings (see Tables 51-4 and 51-5). A normal PTH level almost never occurs with vitamin D deficiency and suggests a primary phosphate disorder.

**Treatment**

Children with nutritional vitamin D deficiency should receive vitamin D and adequate nutritional intake of calcium and phosphorus. There are 2 strategies for administration of vitamin D. With stoss therapy, 300,000-600,000 IU of vitamin D are administered orally or intramuscularly as 2-4 doses over 1 day. Because the doses are observed, stoss therapy is ideal in situations where adherence to therapy is question-able. The alternative is daily, high-dose vitamin D, with doses ranging from 2,000-5,000 IU/day over 4-6 wk. Either strategy should be followed by daily vitamin D intake of 400 IU/day if <1 yr old or 600 IU/day if >1 yr old. It is important to ensure that children receive adequate dietary calcium and phosphorus; this dietary intake is usually provided by milk, formula, and other dairy products.

Children who have symptomatic hypocalcemia might need intravenous calcium acutely, followed by oral calcium supplements, which typically can be tapered over 2-6 wk in children who receive adequate dietary calcium. Transient use of intravenous or oral 1,25-D (calcitriol) is often helpful in reversing hypocalcemia in the acute phase by providing active vitamin D during the delay as supplemental vitamin D is converted to active vitamin D. Calcitriol doses are typically 0.05 µg/kg/day. Intravenous calcium is initially given as an acute bolus for symptomatic hypocalcemia (20 mg/kg of calcium.
chloride or 100 mg/kg of calcium gluconate). Some patients require a continuous intravenous calcium drip, titrated to maintain the desired serum calcium level. These patients should transition to enteral calcium, and most infants require approximately 1,000 mg of elemental calcium.

**Prognosis**

Most children have an excellent response to treatment, with radiologic healing occurring within a few months. Laboratory test results should also normalize rapidly. Many of the bone malformations improve dramatically, but children with severe disease can have permanent deformities and short stature. Rarely, patients benefit from orthopedic intervention for leg deformities, although this is generally not done until the metabolic bone disease has healed, there is clear evidence that the deformity will not self-resolve, and the deformity is causing functional problems.

**Prevention**

Most cases of nutritional rickets can be prevented by universal administration of 400 IU of vitamin D to infants who are breastfed. Older children should receive 600 IU/day. Vitamin D may be administered as a component of a multivitamin or as a vitamin D supplement.

**Congenital Vitamin D Deficiency**

Congenital rickets is quite rare in industrialized countries and occurs when there is severe maternal vitamin D deficiency during pregnancy. Maternal risk factors include poor dietary intake of vitamin D, lack of adequate sun exposure, and closely spaced pregnancies. These newborns can have symptomatic hypocalcemia, intrauterine growth retardation, and decreased bone ossification, along with classic rachitic changes. More subtle maternal vitamin D deficiency can have an adverse effect on neonatal bone density and birthweight, cause a defect in dental enamel, and predispose infants to neonatal hypocalcemic tetany. Treatment of congenital rickets includes vitamin D supplementation and adequate intake of calcium and phosphorus. Use of prenatal vitamins containing vitamin D prevents this entity.

**Secondary Vitamin D Deficiency**

Etiology

Along with inadequate intake, vitamin D deficiency can develop due to inadequate absorption, decreased hydroxylation in the liver, and increased degradation. Because vitamin D is fat-soluble, its absorption may be decreased in patients with a variety of liver and GI diseases, including cholestatic liver disease, defects in bile acid metabolism, cystic fibrosis and other causes of pancreatic dysfunction, celiac disease, and Crohn disease. Malabsorption of vitamin D can also occur with intestinal lymphangiectasia and after intestinal resection.

Severe liver disease, which is usually also associated with malabsorption, can cause a decrease in 25-D formation as a consequence of insufficient enzyme activity. Because of the large reserve of 25-hydroxylase activity in the liver, vitamin D deficiency as a result of liver disease usually requires a loss of >90% of liver function. A variety of medications increase the degradation of vitamin D by inducing the cytochrome P450 system. Rickets as a consequence of vitamin D deficiency can develop in children receiving anticonvulsants, such as phenobarbital or phenytoin, or antituberculosis medications, such as isoniazid or rifampin.

**Treatment**

Treatment of vitamin D deficiency attributable to malabsorption requires high doses of vitamin D. Because of its better absorption, 25-D (25-50 µg/day or 5-7 µg/kg/day) is superior to vitamin D₃. The dose is adjusted based on monitoring of serum levels of 25-D. Alternatively, patients may be treated with 1,25-D, which also is better absorbed in the presence of fat malabsorption, or with parenteral vitamin D. Children with rickets as a result of increased degradation of vitamin D by the cytochrome P450 system require the same acute therapy as indicated for nutritional deficiency (discussed earlier), followed by long-term administration of high doses of vitamin D (e.g., 1,000 IU/day), with dosing titrated based on serum levels of 25-D. Some patients require as much as 4,000 IU/day.

**Vitamin D–Dependent Rickets, Type 1**

Children with vitamin D–dependent rickets type 1, an autosomal recessive disorder, have mutations in the gene encoding renal 1α-hydroxylase, preventing conversion of 25-D into 1,25-D. These patients normally present during the 1st-2yr of life and can have any of the classic features of rickets (see Table 51-3), including asymptomatic hypocalcemia. They have normal levels of 25-D, but low levels of 1,25-D (see Table 51-5). Occasionally, 1,25-D levels are at the lower limit of normal, inappropriately low given the high PTH and low serum phosphorus levels, both of which should increase the activity of renal 1α-hydroxylase and cause elevated levels of 1,25-D. As in nutritional vitamin D deficiency, renal tubular dysfunction can cause a metabolic acidosis and generalized aminoaciduria.

**Treatment**

These patients respond to long-term treatment with 1,25-D (calcitriol). Initial doses are 0.25-2 µg/day, and lower doses are used once the rickets has healed. Especially during initial therapy, it is important to ensure adequate intake of calcium. The dose of calcitriol is adjusted to maintain a low-normal serum calcium level, a normal serum phosphorus level, and a high-normal serum PTH level. Targeting a low-normal calcium concentration and a high-normal PTH level avoids excessive dosing of calcitriol, which can cause hypercalcemia and nephrocalcinosis. Hence, patient monitoring includes periodic assessment of urinary calcium excretion, with a target of <4 mg/kg/day.

**Vitamin D–Dependent Rickets, Type 2**

Patients with vitamin D–dependent rickets type 2 have mutations in the gene encoding the vitamin D receptor, preventing a normal physiologic response to 1,25-D. Levels of 1,25-D are extremely elevated in this autosomal recessive disorder (see Table 51-4). Most patients present during infancy, although rickets in less severely affected patients might not be diagnosed until adulthood. Less-severe disease is associated with a partially functional vitamin D receptor. Approximately 50-70% of children have alopecia, which tends to be associated with a more severe form of the disease and can range from alopecia areata to alopecia totalis. Epidermal cysts are a less common manifestation.

**Treatment**

Some patients respond to extremely high doses of vitamin D₂, 25-D or 1,25-D, especially patients without alopecia. This response is due to a partially functional vitamin D receptor. All patients with this disorder should be given a 3-6 mo trial of high-dose vitamin D and oral calcium. The initial dose of 1,25-D should be 2 µg/day, but some patients require doses as high as 50-60 µg/day. Calcium doses are 1,000-3,000 mg/day. Patients who do not respond to high-dose vitamin D may be treated with long-term intravenous calcium, with possible transition to very high dose oral calcium supplements. Treatment of patients who do not respond to vitamin D is difficult.

**Chronic Kidney Disease (See Chapter 535.2)**

With chronic kidney disease, there is decreased activity of 1α-hydroxylase in the kidney, leading to diminished production of 1,25-D. In chronic kidney disease, unlike the other causes of vitamin D deficiency, patients have hyperphosphatemia as a result of decreased renal excretion (see Table 51-4).

**Treatment**

Therapy requires the use of a form of vitamin D that can act without 1-hydroxylation by the kidney (calcitriol), which both permits adequate absorption of calcium and directly suppresses the parathyroid gland. Because hyperphosphatemia is a stimulus for PTH secretion, normalization of the serum phosphorus level via a combination of dietary phosphorus restriction and the use of oral phosphate binders is as important as the use of activated vitamin D.
**CALCIUM DEFICIENCY**

**Pathophysiology**
Rickets secondary to inadequate dietary calcium is a significant problem in some countries in Africa, although there are cases in other regions of the world, including industrialized countries. Because breast milk and formula are excellent sources of calcium, this form of rickets develops after children have been weaned from breast milk or formula and is more likely to occur in children who are weaned early. Rickets develops because the diet has low calcium content, typically <200 mg/day. There is little intake of dairy products or other sources of calcium. In addition, because of reliance on grains and green leafy vegetables, the diet may be high in phytate, oxalate, and phosphate, which decrease absorption of dietary calcium. In industrialized countries, rickets caused by calcium deficiency can occur in children who consume an unconventional diet. Examples include children with milk allergy who have low dietary calcium and children who transition from formula or breast milk to juice, soda, or a calcium-poor soy drink, without an alternative source of dietary calcium.

This type of rickets can develop in children who receive intravenous nutrition without adequate calcium. Malabsorption of calcium can occur in celiac disease, intestinal abetalipoproteinemia, and after small bowel resection. There may be concurrent malabsorption of vitamin D.

**Clinical Manifestations**
Children have the classic signs and symptoms of rickets (see Table 51-3). Presentation can occur during infancy or early childhood, although some cases are diagnosed in teenagers. Because calcium deficiency occurs after the cessation of breastfeeding, it tends to occur later than the nutritional vitamin D deficiency that is associated with breastfeeding. In Nigeria, nutritional vitamin D deficiency is most common at 4-15 mo of age, whereas calcium-deficiency rickets typically occurs at 15-25 mo of age.

**Diagnosis**
Laboratory findings include increased levels of alkaline phosphatase, PTH, and 1,25-D (see Table 51-4). Calcium levels may be normal or low, although symptomatic hypocalcemia is uncommon. There is decreased urinary excretion of calcium, and serum phosphorus levels may be low as a result of renal wasting of phosphate from secondary hyperparathyroidism. In some children, there is coexisting nutritional vitamin D deficiency, with low 25-D levels.

**Treatment**
Treatment focuses on providing adequate calcium, typically as a dietary supplement (doses of 700 [1-3 yr age], 1,000 [4-8 yr age], 1,300 [9-18 yr age] mg/day of elemental calcium are effective). Vitamin D supplementation is necessary if there is concurrent vitamin D deficiency (discussed earlier). Prevention strategies include discouraging early cessation of breastfeeding and increasing dietary sources of calcium. In countries such as Kenya, where many children have diets high in cereal with negligible intake of cow's milk, school-based milk programs have been effective in reducing the prevalence of rickets.

**PHOSPHOROUS DEFICIENCY**

**Inadequate Intake**
With the exception of starvation or severe anorexia, it is almost impossible to have a diet that is deficient in phosphorus, because phosphorus is present in most foods. Decreased phosphorus absorption can occur in diseases associated with malabsorption (celiac disease, cystic fibrosis, cholestatic liver disease), but if rickets develops, the primary problem is usually malabsorption of vitamin D and/or calcium.

Isolated malabsorption of phosphorus occurs in patients with long-term use of aluminum-containing antacids. These compounds are very effective at chelating phosphate in the GI tract, leading to decreased absorption. This decreased absorption results in hypophosphatemia with secondary osteomalacia in adults and rickets in children. This entity responds to discontinuation of the antacid and short-term phosphorus supplementation.

**Fibroblast Growth Factor-23**
Fibroblast growth factor-23 (FGF-23) is a humoral mediator that decreases renal tubular reabsorption of phosphate and therefore decreases serum phosphorus. FGF-23, synthesized by osteocytes, also decreases the activity of renal 1α-hydroxylase, resulting in a decrease in the production of 1,25-D. Increased levels of FGF-23 cause many of the renal phosphate-wasting diseases (see Table 51-2).

**X-Linked Hypophosphatemic Rickets**
Among the genetic disorders causing rickets because of hypophosphatemia, X-linked hypophosphatemic rickets (XLH) is the most common, with a prevalence of 1/20,000. The defective gene is on the X chromosome, but female carriers are affected, so it is an X-linked dominant disorder.

**Pathophysiology**
The defective gene is called PHEX because it is a Phosphate-regulating gene with homology to Endopeptidases on the X chromosome. The product of this gene appears to have an indirect role in inactivating FGF-23. Mutations in the PHEX gene lead to increased levels of FGF-23. Because the actions of FGF-23 include inhibition of phosphate reabsorption in the proximal tubule, phosphate excretion is increased. FGF-23 also inhibits renal 1α-hydroxylase, leading to decreased production of 1,25-D.

**Clinical Manifestations**
These patients have rickets, but abnormalities of the lower extremities and poor growth are the dominant features. Delayed dentition and tooth abscesses are also common. Some patients have hypophosphatemia and short stature without clinically evident bone disease.

**Laboratory Findings**
Patients have high renal excretion of phosphate, hypophosphatemia, and increased alkaline phosphatase; PTH and serum calcium levels are normal (see Table 51-4). Hypophosphatemia normally upregulates renal 1α-hydroxylase and should lead to an increase in 1,25-D, but these patients have low or inappropriately normal levels of 1,25-D.

**Treatment**
Patients respond well to a combination of oral phosphorus and 1,25-D (calcitriol). The daily need for phosphorus supplementation is 1-3 g of elemental phosphorus divided into 4-5 doses. Frequent dosing helps to prevent prolonged decrements in serum phosphorus because there is a rapid decline after each dose. In addition, frequent dosing decreases diarrhea, a complication of high-dose oral phosphorus. Calcitriol is administered 30-70 ng/kg/day divided into 2 doses.

Complications of treatment occur when there is not an adequate balance between phosphorus supplementation and calcitriol. Excess phosphorus, by decreasing enteral calcium absorption, leads to secondary hyperparathyroidism, with worsening of the bone lesions. In contrast, excess calcitriol causes hypercalcemia and nephrocalcinosis and can even cause hypercalcinemia. Hence, laboratory monitoring of treatment includes serum calcium, phosphorus, alkaline phosphatase, PTH, and urinary calcium, as well as periodic renal ultrasounds to evaluate patients for nephrocalcinosis. Because of variation in the serum phosphorus level and the importance of avoiding excessive phosphorus dosing, normalization of alkaline phosphatase levels is a more useful method of assessing the therapeutic response than measuring serum phosphorus. For children with significant short stature, growth hormone is an effective option. Children with severe deformities might need osteotomies, but these procedures should be done only when treatment has led to resolution of the bone disease.

**Prognosis**
The response to therapy is usually good, although frequent dosing can lead to problems with compliance. Girls generally have less-severe disease than boys, probably because of the X-linked inheritance. Short stature can persist despite healing of the rickets. Adults generally do well with less-aggressive treatment, and some receive calcitriol alone.
Adults with bone pain or other symptoms improve with oral phosphorus supplementation and calcitriol.

**Autosomal Dominant Hypophosphatemic Rickets**

Autosomal dominant hypophosphatemic rickets (ADHR) is much less common than XLH. There is incomplete penetrance and variable age of onset. Patients with ADHR have a mutation in the gene encoding FGF-23 (FGF23). The mutation prevents degradation of FGF-23 by proteases, leading its level to increase. The actions of FGF-23 include decreased reabsorption of phosphate in the renal proximal tubule, which results in hypophosphatemia, and inhibition of the 1α-hydroxylase in the kidney, causing a decrease in 1,25-D3 synthesis.

In ADHR, as in XLH, abnormal laboratory findings are hypophosphatemia, an elevated alkaline phosphatase level, and a low or inappropriately normal 1,25-D3 level (see Table 51-4). Treatment is similar to the approach used in XLH.

**Autosomal Recessive Hypophosphatemic Rickets**

Autosomal recessive hypophosphatemic rickets (ARHR), type 1 is an extremely rare disorder caused by mutations in the gene encoding dentin matrix protein 1 (DMP1). ARHR, type 2 occurs in patients with mutations in the ENPP1 gene. Mutations in ENPP1 also cause generalized arterial calcification of infancy. Both types of ARHR are associated with elevated levels of FGF-23, leading to renal phosphate wasting, hypophosphatemia, and low or inappropriately normal levels of 1,25-D3. Treatment is similar to the approach used in XLH, although monitoring for arterial calcification is prudent in patients with ENPP1 mutations.

**Hereditary Hypophosphatemic Rickets with Hypercalciuria**

Hereditary hypophosphatemic rickets with hypercalciuria is a rare disorder that is mainly found in the Middle East.

**Pathophysiology**

This autosomal recessive disorder is caused by mutations in the gene for a sodium-phosphate cotransporter in the proximal tubule (SLC34A3). The renal phosphate leak causes hypophosphatemia, which then stimulates production of 1,25-D. The high level of 1,25-D increases intestinal absorption of calcium, suppressing PTH. Hypercalciuria ensues as a result of the high absorption of calcium and the low level of PTH, which normally decreases renal excretion of calcium.

**Clinical Manifestations**

The dominant symptoms are rachitic leg abnormalities (see Table 51-3), muscle weakness, and bone pain. Patients can have short stature, with a disproportionate decrease in the length of the lower extremities. The severity of the disease varies, and some family members have no evidence of rickets but have kidney stones secondary to hypercalciuria.

**Laboratory Findings**

Laboratory findings include hypophosphatemia, renal phosphate wasting, elevated serum alkaline phosphatase levels, and elevated 1,25-D3 levels. PTH levels are low (see Table 51-4).

**Treatment**

Therapy relies on oral phosphorus replacement (1-2.5 g/day of elemental phosphorus in 5 divided oral doses). Treatment of the hypophosphatemia decreases serum levels of 1,25-D3 and corrects the hypercalciuria. The response to therapy is usually excellent, with resolution of pain, weakness, and radiographic evidence of rickets.

**Overproduction of FGF-23**

Tumor-induced osteomalacia is more common in adults than in children, where it can produce classic rachitic findings. Most tumors are mesenchymal in origin and are usually benign, small, and located in bone. These tumors secrete FGF-23 and produce a biochemical phenotype that is similar to XLH, including urinary phosphate wasting, hypophosphatemia, elevated alkaline phosphatase levels, and low or inappropriately normal 1,25-D3 levels (see Table 51-4). Curative treatment is excision of the tumor. If the tumor cannot be removed, treatment is identical to that used for XLH.

Renal phosphate wasting leading to hypophosphatemia and rickets (or osteomalacia in adults) is a potential complication in McCune-Albright syndrome, an entity that includes the triad of polyostotic fibrous dysplasia, hyperpigmented macules, and polyendocrinopathy (see Chapter 563). Affected patients have inappropriately low levels of 1,25-D3 and elevated levels of alkaline phosphatase. The renal phosphate wasting and inhibition of 1,25-D3 synthesis are related to the polyostotic fibrous dysplasia. Patients have elevated levels of FGF-23, presumably produced by the dysplastic bone. Hypophosphatemic rickets can also occur in children with isolated polyostotic fibrous dysplasia. Although it is rarely possible, removal of the abnormal bone can cure this disorder in children with McCune-Albright syndrome. Most patients receive the same treatment as children with XLH. Bisphosphonate treatment decreases the pain and fracture risk associated with the bone lesions.

Rickets is an unusual complication of epidermal nevus syndrome (see Chapter 651). Patients have hypophosphatemic rickets due to renal phosphate wasting and also have an inappropriately normal or low level of 1,25-D as a consequence of excessive production of FGF-23. The timing of presentation with rickets varies from infancy to early adolescence. Resolution of hypophosphatemia and rickets has occurred after excision of the epidermal nevi in some patients, but not in others. In most cases, the skin lesions are too extensive to be removed, necessitating treatment with phosphorus supplements and 1,25-D3. Rickets caused by phosphate wasting is an extremely rare complication in children with neurofibromatosis (see Chapter 596).

**Fanconi Syndrome**

Fanconi syndrome is secondary to generalized dysfunction of the renal proximal tubule (see Chapter 529). There are renal losses of phosphate, amino acids, bicarbonate, glucose, urate, and other molecules that are normally reabsorbed in the proximal tubule. Some patients have partial dysfunction, with less generalized losses. The most clinically relevant consequences are hypophosphatemia caused by phosphate losses and proximal renal tubular acidosis caused by bicarbonate losses. Patients have rickets as a result of hypophosphatemia, with exacerbation from the chronic metabolic acidosis, which causes bone dissolution. Failure to thrive is a consequence of both rickets and renal tubular acidosis. Treatment is dictated by the etiology (see Chapter 529).

**Dent Disease (See Chapter 531.3)**

Dent disease is an X-linked disorder usually caused by mutations in the gene encoding a chloride channel that is expressed in the kidney (CLCN5). Some patients have mutations in the OCRL1 gene, which can also cause Lowe syndrome (see Chapter 530). Affected males have variable manifestations, including hematuria, nephrolithiasis, nephrocalcinosis, rickets, and chronic kidney disease. Almost all patients have low-molecular-weight proteinuria and hypercalciuria. Other, less universal abnormalities are aminoaciduria, glycosuria, hypophosphatemia, and hypokalemia. Rickets occurs in approximately 25% of patients, and it responds to oral phosphorus supplements. Some patients also need 1,25-D3, but this treatment should be used cautiously because it can worsen the hypercalciuria.

**Rickets of Prematurity** (See Chapter 106)

Rickets in very-low-birthweight infants has become a significant problem, as the survival rate for this group of infants has increased.

**Pathogenesis**

The transfer of calcium and phosphorus from mother to fetus occurs throughout pregnancy, but 80% occurs during the 3rd trimester. Premature birth interrupts this process, with rickets developing when the...
premature infant does not have an adequate supply of calcium and phosphorus to support mineralization of the growing skeleton.

Most cases of rickets of prematurity occur in infants with a birthweight <1,000 g. It is more likely to develop in infants with lower birthweight and younger gestational age. Rickets occurs because un-supplemented breast milk and standard infant formula do not contain enough calcium and phosphorus to supply the needs of the premature infant. Other risk factors include cholestatic jaundice, a complicated neonatal course, prolonged use of parenteral nutrition, the use of soy formula, and medications such as diuretics and corticosteroids.

**Clinical Manifestations**

Rickets of prematurity occurs 1-4 mo after birth. Infants can have nontraumatic fractures, especially of the legs, arms, and ribs. Most fractures are not suspected clinically. Because fractures and softening of the ribs lead to decreased chest compliance, some infants have respiratory distress due to atelectasis and poor ventilation. This rachitic respiratory distress usually develops >5 wk after birth, distinguishing it from the early-onset respiratory disease of premature infants. These infants have poor linear growth, with negative effects on growth persisting beyond 1 yr of age. An additional long-term effect is enamel hypoplasia. Poor bone mineralization can contribute to dolichocephaly. There may be classic rachitic findings, such as frontal bossing, rachitic rosary, craniotabes, and widened wrists and ankles (see Table 51-3). Most infants with rickets of prematurity have no clinical manifestations, and the diagnosis is based on radiographic and laboratory findings.

**Laboratory Findings**

Because of inadequate intake, the serum phosphorus level is low or low-normal in rickets of prematurity. The renal response is appropriate, with conservation of phosphate leading to a low urine phosphate level; the tubular reabsorption of phosphate is >95%. Most patients have normal levels of 25-D, unless there has been inadequate intake or poor absorption (discussed earlier). The hypophosphatemia stimulates renal 1α-hydroxylase, so levels of 1,25-D are high or high-normal. These high levels can contribute to bone demineralization, because 1,25-D stimulates bone resorption. Serum levels of calcium are low, normal, or high, and patients often have hypercalcemia. Elevated serum calcium levels and hypercalcemia are secondary to increased intestinal absorption and bone dissolution owing to elevation of 1,25-D levels and the inability to deposit calcium in bone because of an inadequate phosphate supply. The hypercalcemia indicates that phosphorus is the limiting nutrient for bone mineralization, although increased provision of phosphorus alone often cannot correct the mineralization defect; increased calcium is also necessary. Hence, there is an inadequate supply of calcium and phosphorus, but the deficiency in phosphorus is greater.

Alkaline phosphatase levels are often elevated, but some affected infants have normal levels. In some instances, normal alkaline phosphatase levels may be secondary to resolution of the bone demineralization because of an adequate mineral supply despite the continued presence of radiologic changes, which take longer to resolve. However, alkaline phosphatase levels may be normal despite active disease. No single blood test is 100% sensitive for the diagnosis of rickets. The diagnosis should be suspected in infants with an alkaline phosphatase level that is >5-6 times the upper limit of normal for adults (unless there is concomitant liver disease) or a phosphorus level <5.6 mg/dL. The diagnosis is confirmed by radiologic evidence of rickets, which is best seen on films of the wrists and ankles. Films of the arms and legs might reveal fractures. The rachitic rosary may be visible on chest x-ray. Unfortunately, x-rays cannot show early demineralization of bone because changes are not evident until there is >20-30% reduction in the bone mineral content.

**Diagnosis**

Because many premature infants have no overt clinical manifestations of rickets, screening tests are recommended. These tests should include weekly measurements of calcium, phosphorus, and alkaline phosphatase. Periodic measurement of the serum bicarbonate concentration is also important, because metabolic acidosis causes dissolution of bone. At least 1 screening x-ray for rickets at 6-8 wk of age is appropriate in infants who are at high risk for rickets; additional films may be indicated in very high risk infants.

**Prevention**

Provision of adequate amounts of calcium, phosphorus, and vitamin D significantly decreases the risk of rickets of prematurity. Parenteral nutrition is often necessary initially in very premature infants. In the past, adequate parenteral calcium and phosphorus delivery was difficult because of limits secondary to insolubility of these ions when their concentrations were increased. Current amino acid preparations allow higher concentrations of calcium and phosphate, decreasing the risk of rickets. Early transition to enteral feedings is also helpful. These infants should receive either human milk fortified with calcium and phosphorus or preterm infant formula, which has higher concentrations of calcium and phosphorus than standard formula. Soy formula should be avoided because there is decreased bioavailability of calcium and phosphorus. Increased mineral feedings should continue until the infant weighs 3-3.5 kg. These infants should also receive approximately 400 IU/day of vitamin D via formula and vitamin supplements.

**Treatment**

Therapy for rickets of prematurity focuses on ensuring adequate delivery of calcium, phosphorus, and vitamin D. If mineral delivery has been good and there is no evidence of healing, then it is important to screen for vitamin D deficiency by measuring serum 25-D. Measurement of PTH, 1,25-D, and urinary calcium and phosphorus may be helpful in some cases.

**DISTAL RENAL TUBULAR ACIDOSIS**

(See Chapter 530)

Distal renal tubular acidosis usually manifests with failure to thrive. Patients have a metabolic acidosis with an inability to acidify the urine appropriately. Hypercalcemia and nephrocalcinosis are typically present. There are many possible etiologies, including autosomal recessive and autosomal dominant forms. Rickets is variable, and it responds to alkali therapy (see Fig. 51-4).

**HYPERVITAMINOSIS D**

**Etiology**

Hypervitaminosis D is secondary to excessive intake of vitamin D. It can occur with long-term high intake or with a substantial, acute ingestion (see Table 51-1). Most cases are secondary to misuse of prescribed or nonprescription vitamin D supplements, but other cases have been secondary to accidental overfortification of milk, contamination of table sugar, and inadvertent use of vitamin D supplements as cooking oil. The recommended upper limits for long-term vitamin D intake are 1,000 IU for children <1 year old and 2,000 IU for older children and adults. Hypervitaminosis D can also result from excessive intake of synthetic vitamin D analogs (25-D, 1,25-D). Vitamin D intoxication is never secondary to excessive exposure to sunlight, probably because ultraviolet irradiation can transform vitamin D3 and its precursor into inactive metabolites.

**Pathogenesis**

Although vitamin D increases intestinal absorption of calcium, the dominant mechanism of the hypercalcemia is excessive bone resorption.

**Clinical Manifestations**

The signs and symptoms of vitamin D intoxication are secondary to hypercalcemia. GI manifestations include nausea, vomiting, poor feeding, constipation, abdominal pain, and pancreatitis. Possible cardiac findings are hypertension, decreased Q-T interval, and arrhythmias. The central nervous system effects of hypercalcemia include lethargy, hypotonia, confusion, disorientation, depression, psychosis, hallucinations, and coma. Hypercalcemia impairs renal concentrating
mechanisms, which can lead to polyuria, dehydration, and hypernatremia. Hypercalcemia can also lead to acute renal failure, nephrolithiasis, and nephrocalcinosis, which can result in chronic renal insufficiency. Deaths are usually associated with arrhythmias or dehydration.

**Laboratory Findings**
The classic findings in vitamin D intoxication are hypercalcemia and extremely elevated levels of 25-D (>150 ng/mL). Hyperphosphatemia is also common. PTH levels are appropriately decreased owing to hypercalcemia. Hypercalciuria is universally present and can lead to nephrocalcinosis, which is visible on renal ultrasound. Hypercalcemia and nephrocalcinosis can lead to renal insufficiency.

Surprisingly, levels of 1,25-D are usually normal. This may be a result of downregulation of renal 1α-hydroxylase by the combination of low PTH, hyperphosphatemia, and a direct effect of 1,25-D. There is evidence indicating that the level of free 1,25-D may be high, owing to displacement from vitamin D–binding proteins by 25-D. Nephrocalcinosis is often visible on ultrasound or CT scan. Anemia is sometimes present; the mechanism is unknown.

**Diagnosis and Differential Diagnosis**
The diagnosis is based on the presence of hypercalcemia and an elevated serum 25-D level, although children with excess intake of 1,25-D or another synthetic vitamin D preparation have normal levels of 25-D. With careful sleuthing, there is usually a history of excess intake of vitamin D, although in some situations (overfortification of milk by a dairy) the patient and family may be unaware.

The differential diagnosis of vitamin D intoxication focuses on other causes of hypercalcemia. Hyperparathyroidism produces hypophosphatemia, whereas vitamin D intoxication usually causes hyperphosphatemia. Williams syndrome is often suggested by phenotypic features and accompanying cardiac disease. Idiopathic infantile hypercalcemia occurs in children taking appropriate doses of vitamin D. Subcutaneous fat necrosis is a common cause of hypercalcemia in young infants; skin findings are usually present. The hypercalcemia of familial benign hypocalciuric hypercalcemia is mild, asymptomatic, and associated with hypocalciuria. Hypercalcemia of malignancy is an important consideration. High intake of calcium can also cause hypercalcemia, especially in the presence of renal insufficiency. Questioning about calcium intake should be part of the history in a patient with hypercalcemia. Occasionally, patients are intentionally taking high doses of calcium and vitamin D.

**Treatment**
The treatment of vitamin D intoxication focuses on control of hypercalcemia. Many patients with hypercalcemia are dehydrated as a result of polyuria from nephrogenic diabetes insipidus, poor oral intake, and vomiting. Rehydration lowers the serum calcium level via dilution and corrects prerenal azotemia. The resultant increased urine output increases urinary calcium excretion. Urinary calcium excretion is also increased by high urinary sodium excretion. The mainstay of the initial treatment is aggressive therapy with normal saline, often in conjunction with a loop diuretic to further increase calcium excretion.

Normal saline, with or without a loop diuretic, is often adequate for treating mild or moderate hypercalcemia. More significant hypercalcemia usually requires other therapies. Glucocorticoids decrease intestinal absorption of calcium by blocking the action of 1,25-D. There is also a decrease in the levels of 25-D and 1,25-D. The usual dosage of prednisone is 1-2 mg/kg/24 hr.

Calcitonin, which lowers calcium by inhibiting bone resorption, is a useful adjunct, but its effect is usually not dramatic. There is an excellent response to intravenous or oral bisphosphonates in vitamin D intoxication. Bisphosphonates inhibit bone resorption through their effects on osteoclasts. Hemodialysis using a low or 0 dialysate calcium can rapidly lower serum calcium in patients with severe hypercalcemia that is refractory to other measures.

Along with controlling hypercalcemia, it is imperative to eliminate the source of excess vitamin D. Additional sources of vitamin D such as multivitamins and fortified foods should be eliminated or reduced.

Avoidance of sun exposure, including the use of sunscreen, is prudent. The patient should also restrict calcium intake.

**Prognosis**
Most children make a full recovery, but hypervitaminosis D may be fatal or can lead to chronic kidney disease. Because vitamin D is stored in fat, levels can remain elevated for months, necessitating regular monitoring of 25-D, serum calcium, and urine calcium.

Vitamin E Deficiency

Larry A. Greenbaum

Vitamin E is a fat-soluble vitamin and functions as an antioxidant, but its precise biochemical functions are not known. Vitamin E deficiency can cause hemolysis or neurologic manifestations and occurs in premature infants, in patients with malabsorption, and in an autosomal recessive disorder affecting vitamin E transport. Because of its role as an antioxidant, there is considerable research on the potential role of vitamin E supplementation in chronic illnesses.

PATHOGENESIS

The term vitamin E denotes a group of 8 compounds with similar structures and antioxidant activity. The most potent member of these compounds is α-tocopherol, which is also the main form in humans. The best dietary sources of vitamin E are vegetable oils, seeds, nuts, green leafy vegetables, and margarine (see Table 51-1).

The majority of vitamin E is located within cell membranes, where it prevents lipid peroxidation and the formation of free radicals. Other antioxidants, such as ascorbic acid, enhance the antioxidant activity of vitamin E. The importance of other functions of vitamin E is still being delineated.

Premature infants are particularly susceptible to vitamin E deficiency, because there is significant transfer of vitamin E during the last trimester of pregnancy. Vitamin E deficiency in premature infants causes thrombocytosis, edema, and hemolysis potentially causing anemia. The risk of symptomatic vitamin E deficiency was increased by the use of formulas for premature infants that had a high content of polyunsaturated fatty acids (PUFAs). These formulas led to a high content of PUFAs in red blood cell membranes, making them more susceptible to oxidative stress, which could be ameliorated by vitamin E. Oxidative stress was augmented by aggressive use of iron supplementation; iron increases the production of oxygen radicals. The incidence of hemolysis as a result of vitamin E deficiency in premature infants decreased secondary to the use of formulas with a lower content of PUFAs, less-aggressive use of iron, and provision of adequate vitamin E.

Because vitamin E is plentiful in common foods, primary dietary deficiency is rare except in premature infants and in severe, generalized malnutrition. Vitamin E deficiency does occur in children with fat malabsorption secondary to the need for bile acid for vitamin E absorption. Although symptomatic disease is most common in children with cholestatic liver disease, it can occur in patients with cystic fibrosis, celiac disease, short-bowel syndrome, or Crohn disease. The autosomal recessive disorder abetalipoproteinemia (see Chapter 86) causes fat malabsorption, and vitamin E deficiency is a common complication.
In **ataxia with isolated vitamin E deficiency** (AVED), a rare autosomal recessive disorder, there are mutations in the gene for α-tocopherol transfer protein (TTPA). Patients with this disorder are unable to incorporate vitamin E into lipoproteins before their release from the liver, leading to reduced serum levels of vitamin E. There is no associated fat malabsorption, and absorption of vitamin E from the intestine occurs normally.

**CLINICAL MANIFESTATIONS**

A severe, progressive neurologic disorder occurs in patients with prolonged vitamin E deficiency. Clinical manifestations do not appear until after 1 yr of age, even in children with cholestasis since birth. Patients may have cerebellar disease, posterior column dysfunction, and retinal disease. Loss of deep tendon reflexes is usually the initial finding. Subsequent manifestations include limb ataxia (intention tremor, dysdiadochokinesia), truncal ataxia (wide-based, unsteady gait), dysarthria, ophthalmoplegia (limited upward gaze), nystagmus, decreased proprioception (positive Romberg test), decreased vibratory sensation, and dysarthria. Some patients have pigmentary retinopathy. Visual field constriction can progress to blindness. Cognition and behavior can also be affected. Myopathy and cardiac arrhythmias are less-common findings.

In premature infants, hemolysis as a result of vitamin E deficiency typically develops during the 2nd mo of life. Edema may also be present.

**LABORATORY FINDINGS**

Serum vitamin E levels increase in the presence of high serum lipid levels, even when vitamin E deficiency is present. Hence, vitamin E status is best determined by measuring the ratio of vitamin E to serum lipids; a ratio <0.8 mg/g is abnormal in older children and adults; <0.6 mg/g is abnormal in infants <1 yr. Premature infants with hemolysis caused by vitamin E deficiency also often have elevated platelet counts.

Neurologic involvement can cause abnormal somatosensory evoked potentials and nerve conduction studies. Abnormalities on electroretinography can precede physical examination findings in patients with retinal involvement.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

Premature infants with unexplained hemolytic anemia after the 1st mo of life, especially if thrombocytosis is present, either should be empirically treated with vitamin E or should have serum vitamin E and lipid levels measured. Children with neurologic findings and a disease that causes fat malabsorption should have their vitamin E status evaluated.

Because children with AVED do not have symptoms of malabsorption, a correct diagnosis requires a high index of suspicion. **Friedreich ataxia** has been misdiagnosed in some patients (see Chapter 597.1). Children with unexplained ataxia should be screened for vitamin E deficiency.

**TREATMENT**

For correction of deficiency in neonates, the dose of vitamin E is 25-50 units/day for 1 wk, followed by adequate dietary intake. Children with deficiency as a result of malabsorption should receive 1 unit/kg/day, with the dose adjusted based on levels; ongoing treatment is necessary. Children with AVED normalize their serum vitamin E levels with high doses of vitamin E and require ongoing treatment.

**PROGNOSIS**

The hemolytic anemia in infants resolves with correction of the vitamin E deficiency. Some neurologic manifestations of vitamin E deficiency may be reversible with early treatment, but many patients have little or no improvement. Importantly, treatment prevents progression.

**PREVENTION**

Premature infants should receive sufficient vitamin E via formula or breast milk fortifier and formula without a high content of PUFAs.

Chapter 53
Vitamin K Deficiency
Larry A. Greenbaum

Vitamin K is necessary for the synthesis of clotting factors II, VII, IX, and X; deficiency of vitamin K can result in clinically significant bleeding. Vitamin K deficiency typically affects infants, who experience a transient deficiency related to inadequate intake, or patients of any age who have decreased vitamin K absorption. Mild vitamin K deficiency can affect long-term bone and vascular health (see Chapters 103.4 and 480).

**PATHOGENESIS**

Vitamin K is a group of compounds that have a common naphthoquinone ring structure. Phylloquinone, called vitamin $K_1$, is present in a variety of dietary sources, with green leafy vegetables, liver, and certain legumes and plant oils having the highest content. Vitamin $K_1$ is the form used to fortify foods and as a medication in the United States. Vitamin $K_2$ is a group of compounds called menaquinones, which are produced by intestinal bacteria. There is uncertainty regarding the relative importance of intestinally produced vitamin $K_2$. Menaquinones are also present in meat, especially liver, and cheese. A menaquinone is used pharmacologically in some countries.

Vitamin K is a cofactor for $\gamma$-glutamyl carboxylase, an enzyme that performs posttranslational carboxylation, converting glutamate residues in proteins to $\gamma$-carboxyglutamate (Gla). The Gla residues, by facilitating calcium binding, are necessary for protein function.

The classic Gla-containing proteins involved in blood coagulation that are decreased in vitamin K deficiency are factors II (prothrombin), VII, IX, and X. Vitamin K deficiency causes a decrease in proteins C and S, which inhibit blood coagulation, and protein Z, which also has a role in coagulation. All of these proteins are made only in the liver, except for protein S, a product of various tissues.

Gla-containing proteins are also involved in bone biology (e.g., osteocalcin and protein S) and vascular biology (matrix Gla protein and protein S). Based on the presence of reduced levels of Gla, these proteins appear more sensitive than the coagulation proteins to subtle vitamin K deficiency. There is evidence suggesting that mild vitamin K deficiency might have a deleterious effect on long-term bone strength and vascular health.

Because it is fat soluble, vitamin K requires the presence of bile salts for its absorption. Unlike other fat-soluble vitamins, there are limited body stores of vitamin K. In addition, there is high turnover of vitamin K, and the vitamin $K$–dependent clotting factors have a short half-life. Hence, symptomatic vitamin K deficiency can develop within weeks when there is inadequate supply because of low intake or malabsorption.

There are 3 forms of vitamin K–deficiency bleeding (VKDB) of the newborn (see Chapter 103.4). Early VKDB was formerly called classic hemorrhagic disease of the newborn and occurs at 1-14 days of age. Early VKDB is secondary to low stores of vitamin K at birth as a result of the poor transfer of vitamin K across the placenta and inadequate intake during the 1st few days of life. In addition, there is no intestinal synthesis of vitamin $K_1$ because the newborn gut is sterile. Early VKDB
occurs mostly in breastfed infants as a consequence of the low vitamin K content of breast milk (formula is fortified). Delayed feeding is an additional risk factor.

Late VKDB most commonly occurs at 2-12 wk of age, although cases can occur up to 6 mo after birth. Almost all cases are in breastfed infants because of the low vitamin K content of breast milk. An additional risk factor is occult malabsorption of vitamin K, as occurs in children with undiagnosed cystic fibrosis or cholestatic liver disease (e.g., biliary atresia, α₁-antitrypsin deficiency). Without vitamin K prophylaxis, the incidence is 4-10/100,000 newborns.

The third form of VKDB of the newborn occurs at birth or shortly thereafter. It is secondary to maternal intake of medications (warfarin, phenobarbital, phenytol) that cross the placenta and interfere with vitamin K function.

VKDB as a result of fat malabsorption can occur in children of any age. Potential etiologies include cholestatic liver disease, pancreatic disease, and intestinal disorders (celiac sprue, inflammatory bowel disease, short-bowel syndrome). Prolonged diarrhea can cause vitamin K deficiency, especially in breastfed infants. Children with cystic fibrosis are most likely to have vitamin K deficiency if they have pancreatic insufficiency and liver disease.

Beyond infancy, low dietary intake by itself never causes vitamin K deficiency. However, the combination of poor intake and the use of broad-spectrum antibiotics that eliminate the intestine's vitamin K-producing bacteria can cause vitamin K deficiency. This scenario is especially common in the intensive care unit. Vitamin K deficiency can also occur in patients who receive total parenteral nutrition without vitamin K supplementation.

CLINICAL MANIFESTATIONS
In early VKDB, the most common sites of bleeding are the gastrointestinal (GI) tract, mucosal and cutaneous tissue, the umbilical stump, and the postcircumcision site; intracranial bleeding is less common. GI blood loss can be severe enough to require a transfusion. In contrast, the most common site of bleeding in late VKDB is intracranial, although cutaneous and GI bleeding may be the initial manifestation. Intracranial bleeding can cause convulsions, permanent neurologic sequelae, or death. In some cases of late VKDB, the presence of an underlying disorder may be suggested by jaundice or failure to thrive. Older children with vitamin K deficiency can present with bruising, mucocutaneous bleeding, or more serious bleeding.

LABORATORY FINDINGS
In patients with bleeding as a result of vitamin K deficiency, the prothrombin time (PT) is prolonged. The PT must be interpreted based on the patient's age, because it is normally prolonged in newborns (see Chapter 476). The partial thromboplastin time is usually prolonged, but it may be normal in early deficiency; factor VII has the shortest half-life of the coagulation factors and is the first to be affected by vitamin K deficiency, but isolated factor VII deficiency does not affect the partial thromboplastin time. The platelet count and fibrinogen level are normal.

When there is mild vitamin K deficiency, the PT is normal, but there are elevated levels of the undercarboxylated forms of the proteins that are normally carboxylated in the presence of vitamin K. These undercarboxylated proteins are called proteins induced by vitamin K absence (PIVKA). Measurement of undercarboxylated factor II (PIVKA-II) can be used to detect mild vitamin K deficiency. Determination of blood vitamin K levels is less useful because of significant variation based on recent dietary intake; levels do not always reflect tissue stores.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
The diagnosis is established by the presence of a prolonged PT that corrects rapidly after administration of vitamin K, which stops the active bleeding. Other possible causes of bleeding and a prolonged PT include disseminated intravascular coagulation (DIC), liver failure, and rare hereditary deficiencies of clotting factors. DIC, which is most commonly secondary to sepsis, is associated with thrombocytopenia, low fibrinogen, and elevated D-dimers. Most patients with DIC have hemodynamic instability that does not correct with restoration of blood volume. Severe liver disease results in decreased production of clotting factors; the PT does not fully correct with administration of vitamin K. Children with a hereditary disorder have a deficiency in a specific clotting factor (I, II, V, VII, X).

Coumarin derivatives inhibit the action of vitamin K by preventing its recycling to an active form after it functions as a cofactor for γ-glutamyl carboxylase. Bleeding can occur with overdosage of the commonly used anticoagulant warfarin or with ingestion of rodent poison, which contains a coumarin derivative. High doses of salicylates also inhibit vitamin K activity, potentially leading to a prolonged PT and clinical bleeding.

TREATMENT
Infants with VKDB should receive 1 mg of parenteral vitamin K. The PT should decrease within 6 hr and normalize within 24 hr. For rapid correction in adolescents, the parenteral dose is 2.5-10 mg. In addition to vitamin K, a patient with severe, life-threatening bleeding should receive an infusion of fresh-frozen plasma, which corrects the coagulopathy rapidly. Children with vitamin K deficiency as a consequence of malabsorption require chronic administration of high doses of oral vitamin K (2.5 mg twice/wk to 5 mg/day). Parenteral vitamin K may be necessary if oral vitamin K is ineffective.

PREVENTION
Administration of either oral or parenteral vitamin K soon after birth prevents early VKDB of the newborn. In contrast, a single dose of oral vitamin K does not prevent a substantial number of cases of late VKDB. However, a single intramuscular injection of vitamin K (1 mg), the current practice in the United States, is almost universally effective, except in children with severe malabsorption. This increased efficacy of the intramuscular form is thought to be the result of a depot effect. Concerns about an association between parenteral vitamin K at birth and the later development of malignancy are unsubstantiated.

Discontinuing the offending medications before delivery can prevent VKDB attributable to maternal medications. If this is not possible, administration of vitamin K to the mother may be helpful. In addition, the neonate should receive parenteral vitamin K immediately after birth. If parenteral vitamin K does not correct the coagulopathy rapidly, then the child should receive fresh frozen plasma.

Children who are at high risk for malabsorption of vitamin K should receive supplemental vitamin K and periodic measurement of the PT.

Bibliography is available at Expert Consult.
Bibliography
Micronutrients include vitamins (see Chapters 48-53) and trace elements. By definition, a trace element is <0.01% of the body weight. Trace elements have a variety of essential functions (Table 54-1). With the exception of iron deficiency, trace element deficiency (see Table 54-1) is uncommon in developed countries, but some deficiencies (iodine, zinc, selenium) are important public health problems in a number of developing countries. Because of low nutritional requirements and plentiful supply, deficiencies of some of the trace elements are extremely rare in humans and typically occur in patients receiving
unusual diets or prolonged total parenteral nutrition without adequate delivery of a specific trace element. They can also occur in children with short bowel or malabsorption. Excess intake of trace elements (see Table 54-1) is uncommon, but it can result from environmental exposure or overuse of supplements.

For a number of reasons, children are especially susceptible to trace element deficiency. First, growth creates an increased demand for most trace elements. Second, some organs are more likely to sustain permanent damage because of trace element deficiency during childhood. The developing brain is particularly vulnerable to the consequences of certain deficiency states (iron, iodide). Similarly, adequate fluoride is most critical for dental health during childhood. Third, as children in the developing world, are more prone to gastrointestinal disorders that can cause trace element deficiencies because of malabsorption.

A normal diet provides adequate intake of most trace elements. However, the intake of certain trace elements varies significantly in different geographic locations. Iodide-containing food is plentiful near the ocean, but inland areas often have inadequate sources, leading to goiter and hypothyroidism. Iodine deficiency is not a problem in the United States because of the widespread use of iodized salt; however, symptomatic iodine deficiency (goiter and hypothyroidism) is common in many developing countries. Selenium content of the soil and consequently of food is also quite variable. Dietary selenium deficiency (associated with cardiomyopathy) occurs in certain locations, such as some parts of China.

The consequences of severe isolated trace mineral deficiency are illustrated in certain genetic disorders. The manifestations of Menkes disease (see Chapters 357.5 and 599) are caused by a mutation in the gene coding for a protein that facilitates intestinal copper absorption. This mutation results in severe copper deficiency; subcutaneous copper is an effective treatment. The recessive disorder acrodermatitis enteropathica (see Chapter 671) is secondary to malabsorption of zinc. These patients respond dramatically to zinc supplementation.

Children can have apparently asymptomatic deficiencies of certain trace elements but still benefit from supplementation. As an example, zinc is highly effective in treating children before or during diarrheal illnesses in the developing world.

*These deficiency states have been reported only in case reports associated with parenteral nutrition or highly unusual diets.
Zinc deficiency is quite common in the developing world and is often associated with malnutrition or other micronutrient deficiencies (iron). Chronic zinc deficiency is associated with dwarfism, hypogonadism, dermatitis, and T-cell immunodeficiency. Diets rich in phytates bind zinc, impairing its absorption. Zinc supplementation in at-risk children reduces the incidence and severity of diarrhea, pneumonia, and possibly malaria. In developing countries, children who have diarrhea may benefit from zinc supplementation, especially if there is underlying malnutrition.

Chapter 55
Electrolyte and Acid-Base Disorders

55.1 Composition of Body Fluids
Larry A. Greenbaum

TOTAL BODY WATER
Total body water (TBW) as a percentage of body weight varies with age (Fig. 55-1). The fetus has very high TBW, which gradually decreases to approximately 75% of birthweight for a term infant. Premature infants have higher TBW than term infants. During the 1st yr of life, TBW decreases to approximately 60% of body weight and basically remains at this level until puberty. At puberty, the fat content of females increases more than that in males, who acquire more muscle mass than females. Because fat has very low water content and muscle has high water content, by the end of puberty TBW in males remains at 60%, but TBW in females decreases to approximately 50% of body weight. The high fat content in overweight children causes a decrease in TBW as a percentage of body weight. During dehydration, TBW decreases and, thus, is a smaller percentage of body weight.

FLUID COMPARTMENTS
TBW is divided between 2 main compartments: intracellular fluid (ICF) and extracellular fluid (ECF). In the fetus and newborn, the ECF volume is larger than the ICF volume (see Fig. 55-1). The normal postnatal diuresis causes an immediate decrease in the ECF volume. This is followed by continued expansion of the ICF volume, which results from cellular growth. By 1 yr of age, the ratio of the ICF volume to the ECF volume approaches adult levels. The ECF volume is approximately 20-25% of body weight, and the ICF volume is approximately 30-40% of body weight, close to twice the ECF volume (Fig. 55-2). With puberty, the increased muscle mass of males causes them to have a higher ICF volume than females. There is no significant difference in the ECF volume between postpubertal females and males.

The ECF is further divided into the plasma water and the interstitial fluid (see Fig. 55-2). The plasma water is 5% of body weight. The blood volume, given a hematocrit of 40%, is usually 8% of body weight, although it is higher in newborns and young infants; in premature newborns, it is approximately 10% of body weight. The volume of plasma water can be altered by pathologic conditions, including dehydration, anemia, polythemia, heart failure, abnormal plasma osmolality, and hypoalbuminemia. The interstitial fluid, normally 15% of body weight, can increase dramatically in diseases associated with edema, such as heart failure, protein-losing enteropathy, liver failure, nephrotic syndrome, and sepsis. An increase in interstitial fluid also occurs in patients with ascites or pleural effusions.

There is a delicate equilibrium between the intravascular fluid and the interstitial fluid. The balance between hydrostatic and oncotic forces regulates the intravascular volume, which is critical for proper tissue perfusion. The intravascular fluid has a higher concentration of albumin than the interstitial fluid, and the consequent oncotic force draws water into the intravascular space. The maintenance of this gradient depends on the limited permeability of albumin across the capillaries. The hydrostatic pressure of the intravascular space, which is due to the pumping action of the heart, drives fluid out of the intravascular space. These forces favor movement into the interstitial space at the arterial ends of the capillaries. The decreased hydrostatic forces and increased oncotic forces, which result from the dilutional increase in albumin concentration, cause movement of fluid into the venous ends of the capillaries. Overall, there is usually a net movement of fluid out of the intravascular space to the interstitial space, but this fluid is returned to the circulation via the lymphatics. An imbalance in these forces may cause expansion of the interstitial volume at the expense of the intravascular volume. In children with hypoalbuminemia, the decreased oncotic pressure of the intravascular fluid contributes to the development of edema. Loss of fluid from the intravascular space may compromise the intravascular volume, placing the child at risk for inadequate blood flow to vital organs. This is especially likely in diseases in which capillary leak occurs because the loss of albumin from the intravascular space is associated with an increase in the albumin concentration in the interstitial space, further compromising the oncotic forces that normally maintain intravascular volume. In contrast, with heart failure, there is an increase in venous hydrostatic pressure from expansion of the intravascular volume, which is caused by impaired pumping by the heart, and the increase in venous pressure causes fluid to move from the intravascular space to the interstitial space. Expansion of the intravascular volume and increased intravascular pressure also cause the edema that occurs with acute glomerulonephritis.

ELECTROLYTE COMPOSITION
The composition of the solutes in the ICF and ECF are very different (Fig. 55-3). Sodium and chloride are the dominant cation and anion, respectively, in the ECF. The sodium and chloride concentrations in the ICF are much lower. Potassium is the most abundant cation in the ICF, and its concentration within the cells is approximately 30 times higher than in the ECF. Proteins, organic anions, and phosphate are the most plentiful anions in the ICF. The dissimilarity between the anions in the ICF and the ECF is largely determined by the presence of intracellular molecules that do not cross the cell membrane, the barrier separating the ECF and the ICF. In contrast, the difference in the distribution of cations—sodium and potassium—is a result of the activity of the Na⁺,K⁺-adenosine triphosphatase (ATPase) pump, which uses cellular energy to actively extrude sodium from cells and move potassium into cells. The chemical gradient between the intracellular potassium concentration and the extracellular potassium concentration creates the electrical gradient across the cell membrane. The concentration-dependent movement of potassium out of the cell makes the intracellular space negative relative to the extracellular space.

The difference in the electrolyte compositions of the ECF and the ICF has important ramifications in the evaluation and treatment of electrolyte disorders. The serum concentration of an electrolyte, which is measured clinically, does not always reflect the body content. This is because of the larger volume of the ICF compared with the ECF and the variation in electrolyte concentrations between these 2 compartments. The intracellular potassium concentration is much higher than the serum concentration. A shift of potassium from the intracellular space can maintain a normal or even an elevated serum potassium concentration, despite massive losses of potassium from the intracellular space. This is dramatically seen in diabetic ketoacidosis, in which a state of significant potassium depletion is often masked because of a transmembrane shift of potassium from the ICF to the ECF. For potassium and phosphorus, electrolytes with a high intracellular concentration, the serum level may not reflect total body content. Similarly, the serum calcium concentration does not predict the body content of calcium, which is largely in bone.
Electrolyte and Acid-Base Disorders

Chapter 55

Electrolyte and Acid-Base Disorders

Osmolality

The ICF and the ECF are in osmotic equilibrium because the cell membrane is permeable to water. If the osmolality in 1 compartment changes, then water movement leads to a rapid equalization of osmolality. This can lead to significant shifts of water between the intracellular space and the extracellular space. Clinically, the primary process is usually a change in the osmolality of the ECF, with a resultant shift of water into the ICF if the ECF osmolality decreases or a shift of water out of the ICF if the ECF osmolality increases. The osmolality of the ECF can be determined, and it usually equals the ICF osmolality. The plasma osmolality is normally 285-295 mOsm/kg, and it is measured by the degree of freezing point depression. The plasma osmolality can also be estimated by a calculation based on the following formula:

\[ \text{Osmolality} = \frac{2 \times [\text{Na}] + [\text{glucose}]}{18} + \frac{[\text{BUN}]}{2.8} \]

Glucose and blood urea nitrogen (BUN) are measured in mg/dL. Division of these values by 18 and 2.8, respectively, as shown, converts the units into mmol/L. Multiplication of the sodium value by 2 accounts for its accompanying anions, principally chloride and bicarbonate. The calculated osmolality is usually slightly lower than the measured osmolality.

Glucose and urea normally contribute little to the plasma osmolality; multiplication of the sodium value by 2 provides an approximation of the osmolality. Urea is not confined to the extracellular space because it readily crosses the cell membrane and its intracellular concentration approximately equals its extracellular concentration. Whereas an elevated sodium concentration causes a shift of water from the intracellular space, with uremia, there is no osmolar gradient between the 2 compartments and, consequently, no movement of water. The only exception is during hemodialysis, when the decrease in extracellular urea is so rapid that the intracellular urea does not have time to equilibrate. This may lead to the disequilibrium syndrome, in which water shifts into brain cells, potentially causing severe symptoms. Ethanol, because it freely crosses cell membranes, is another ineffective osmole. The effective osmolality can be calculated as follows:

\[ \text{Effective osmolality} = 2 \times [\text{Na}] + [\text{glucose}] / 18 \]

The effective osmolality (also called the tonicity) determines the osmotic force that is mediating the shift of water between the ECF and the ICF.

Hyperglycemia causes an increase in the plasma osmolality because it is not in equilibrium with the intracellular space. During hyperglycemia there is a shift of water from the intracellular space to the extracellular space. This is clinically important in children with hyperglycemia during diabetic ketoacidosis. The shift of water causes dilution of the sodium in the extracellular space, causing hyponatremia despite an elevated plasma osmolality. The magnitude of this effect can be calculated as follows:

\[ [\text{Na}]_{\text{corrected}} = [\text{Na}]_{\text{measured}} + 1.6 \times ([\text{glucose}] - 100 \text{ mg/dL}) / 100 \]

where \([\text{Na}]_{\text{measured}}\) is sodium concentration measured by the clinical laboratory and \([\text{Na}]_{\text{corrected}}\) is corrected sodium concentration (the
sodium concentration if the glucose concentration were normal and its accompanying water moved back into the cells). The $[\text{Na}]_{\text{corrected}}$ is the more reliable indicator of the patient’s true ratio of total body sodium to TBW, the normal determinant of the sodium concentration.

Normally, the measured osmolality and the calculated osmolality are within 10 mOsm/kg. However, there are some clinical situations in which this does not occur. The presence of unmeasured osmolytes causes the measured osmolality to be significantly elevated in comparison with the calculated osmolality. This difference is the osmolar gap, which is present when the measured osmolality exceeds the calculated osmolality by >10 mOsm/kg. Examples of unmeasured osmolytes include ethanol, ethylene glycol, methanol, sucrose, sorbitol, and mannitol. These substances increase the measured osmolality but are not part of the equation for calculating osmolality. The presence of an osmolar gap is a clinical clue to the presence of unmeasured osmolytes and may be diagnostically useful when there is clinical suspicion of poisoning with methanol or ethylene glycol.

**Pseudohyponatremia** is a second situation in which there is discordance between the measured osmolality and the calculated osmolality. Lipids and proteins are the solids of the serum. In patients with elevated serum lipids or proteins, the water content of the serum decreases because water is displaced by the larger amount of solids. Some instruments measure sodium concentration by determining the amount of sodium per liter of serum, including the solid component. When the solid component increases, there is a decrease in the sodium concentration per liter of serum, despite a normal concentration of sodium when based on the amount of sodium per liter of serum water. It is the concentration of sodium in serum water that is physiologically relevant. A similar problem occurs when using instruments that require dilution of the sample prior to measurement of sodium (indirect potentiometry). In both situations, the plasma osmolality is normal despite the presence of pseudohyponatremia, because the method for measuring osmolality is not appreciably influenced by the percentage of serum that is composed of lipids and proteins. Pseudohyponatremia is diagnosed by the finding of a normal measured plasma osmolality despite hyponatremia. This laboratory artifact does not occur if the sodium concentration in water is measured directly with an ion-specific electrode, such as occurs with the instruments used for measuring arterial blood gases. **Pseudohypernatremia** may occur in patients with very low levels of serum proteins via a similar mechanism.

When there are no unmeasured osmolytes and pseudohyponatremia is not a concern, the calculated osmolality provides an accurate estimate of the plasma osmolality. Measurement of plasma osmolality is useful for detecting or monitoring unmeasured osmolytes and confirming the presence of true hyponatremia. Whereas many children with high plasma osmolality are dehydrated—as seen with hypernatremic dehydration or diabetic ketoacidosis—high osmolality does not always equate with dehydration. A child with *salt poisoning* or *uremia* has an elevated plasma osmolality but may be volume overloaded. In many situations, it is best to focus on the components of the plasma osmolality and to analyze them individually to reach a correct clinical conclusion.

## 55.2 Regulation of Osmolality and Volume

_Larry A. Greenbaum_

The regulation of plasma osmolality and the intravascular volume is controlled by independent systems for water balance, which determines osmolality, and sodium balance, which determines volume status. Maintenance of normal osmolality depends on control of water balance. Control of volume status depends on regulation of sodium balance. When volume depletion is present, it takes precedence over regulation of osmolality, and retention of water contributes to the maintenance of intravascular volume.

### REGULATION OF OSMOLALITY

The plasma osmolality is tightly regulated and maintained at 285-295 mOsm/kg. Modification of water intake and excretion maintains normal plasma osmolality. In the steady state, the combination of water intake and water produced by the body from oxidation balances water losses from the skin, lungs, urine, and gastrointestinal tract. Only water intake and urinary losses can be regulated.

Osmoreceptors in the hypothalamus sense the plasma osmolality (see Chapter 556). An elevated effective osmolality leads to secretion of antidiuretic hormone (ADH) by neurons in the supraoptic and paraventricular nuclei in the hypothalamus. The axons of these neurons terminate in the posterior pituitary. Circulating ADH binds to its V2 receptors in the collecting duct cells of the kidney, and, via the generation of cyclic adenosine monophosphate, causes insertion of water channels (aquaporin-2) into the renal collecting ducts. This produces increased permeability to water, permitting resorption of water into the hypertonic renal medulla. The end result is that the urine concentration increases and water excretion decreases. Urinary water losses cannot be completely eliminated because there is obligatory excretion of urinary solutes, such as urea and sodium. The regulation of ADH secretion is tightly linked to plasma osmolality, responses being detectable with a 1% change in the osmolality. ADH secretion virtually disappears when the plasma osmolality is low, allowing excretion of maximally dilute urine. The consequent loss of free water (water without sodium) corrects the plasma osmolality. ADH secretion is not an all-or-nothing response; there is a graded adjustment as the osmolality changes.

Production of concentrated urine under the control of ADH requires a hypertonic renal medulla. The countercurrent multiplier, produced by the loop of Henle and the vasa recta, generates this hypertonicity. ADH stimulates sodium transport in the loop of Henle, helping to maintain this gradient when water retention is necessary.

Water intake is regulated by hypothalamic osmoreceptors, although these are different from the osmoreceptors that determine ADH secretion. These hypothalamic osmoreceptors, by linking to the cerebral cortex, stimulate thirst when the serum osmolality increases. Thirst occurs with a small increase in the serum osmolality.

**Control of osmolality is subordinate to maintenance of an adequate intravascular volume.** When volume depletion is present, both ADH secretion and thirst are stimulated, regardless of the plasma osmolality. The sensation of thirst requires moderate volume depletion but only a 1-2% change in the plasma osmolality. Although all of the mechanisms are not clear, angiotensin II, which is increased during volume depletion, is known to stimulate thirst. Baroreceptors, when sensing volume depletion, may also stimulate thirst.

A number of conditions can limit the kidney’s ability to excrete adequate water to correct low plasma osmolality. In the **syndrome of inappropriate antidiuretic hormone (SIADH)**, ADH continues to be produced despite a low plasma osmolality. In the presence of ADH, urinary dilution does not occur, and sufficient water is not excreted (see Chapters 55.5 and 559).

The glomerular filtration rate (GFR) affects the kidney’s ability to eliminate water. With a decrease in the GFR, less water is delivered to the collecting duct, limiting the amount of water that can be excreted. The impairment in the GFR must be quite significant to limit the kidney’s ability to respond to an excess of water.

The **minimum urine osmolality** is approximately 30-50 mOsm/kg. This places an upper limit on the kidney’s ability to excrete water; sufficient solute must be present to permit water loss. Massive water intoxication may exceed this limit, whereas a lesser amount of water is necessary in the child with a diet that has very little solute. This is occasionally seen and can produce severe hyponatremia in children who receive little salt and have little urea production as a result of inadequate protein intake. Volume depletion is an extremely important cause of decreased water loss by the kidney despite a low plasma osmolality. This “appropriate” secretion of ADH occurs because volume depletion takes precedence over the osmolality in the regulation of ADH.

The normal response to increased plasma osmolality is conservation of water by the kidney. In **central diabetes insipidus**, this does not
Bibliography

occurs because of an absence of ADH secretion (see Chapters 55.3 and 558). Patients with *nephrogenic diabetes insipidus* have an inability to respond to ADH and produce dilute urine despite an increase in plasma osmolality (see Chapters 55.3 and 530).

The **maximum urine osmolality** is approximately 1,200 mOsm/kg. The obligatory solute losses dictate the minimum volume of urine that must be produced, even when maximally concentrated. Obligatory water losses increase in patients with high salt intake or high urea losses, as may occur after relief of a urinary obstruction or during recovery from acute tubular necrosis. An increase in urinary solute and, consequently, water losses occurs with an **osmotic diuresis**, which occurs classically from glycosuria in diabetes mellitus as well as iatrogenically after mannitol administration. There are developmental changes in the kidney's ability to concentrate the urine. The maximum urine osmolality in a newborn, especially a premature newborn, is less than that in an older infant or child. This limits the ability to conserve water and makes such a patient more vulnerable to hypernephremic dehydration. Very high fluid intake, as seen with **psychogenic polydipsia**, can dilute the high osmolality in the renal medulla, which is necessary for maximal urinary concentration. If fluid intake is restricted in patients with this condition, there may be some impairment in the kidney's ability to concentrate the urine, although this defect corrects after a few days without polydipsia. This may also occur during the initial treatment of central diabetes insipidus with desmopressin acetate; the renal medulla takes time to achieve its normal maximum osmolality. Loop diuretics, such as furosemide, by inhibiting sodium resorption in the ascending limb of the loop of Henle, decrease medullary hypertonicity, preventing excretion of maximally concentrated urine.

**REGULATION OF VOLUME**

An appropriate intravascular volume is critical for survival; both volume depletion and volume overload may cause significant morbidity and mortality. Because sodium is the principal extracellular cation and it is restricted to the ECF, adequate body sodium is necessary for maintenance of intravascular volume. The principal extracellular anion, chloride, is also necessary, but for simplicity, sodium balance is considered the main regulator of volume status because body content of sodium and that of chloride usually change proportionally, given the need for equal numbers of cations and anions. In some situations, chloride depletion is considered the dominant derangement causing volume depletion (metabolic alkalosis with volume depletion). In other situations, such as volume depletion with metabolic acidosis, sodium depletion may exceed chloride depletion.

The kidney determines sodium balance because there is little homeostatic control of sodium intake, even though salt craving does occasionally occur, typically in children with chronic renal salt loss. The kidney regulates sodium balance by altering the percentage of filtered sodium that is resorbed along the nephron. Normally, the kidney excretes <1% of the sodium filtered at the glomerulus. In the absence of disease, extrarenal losses and urinary output match intake, with the kidney having the capacity to adapt to large variations in sodium intake. When necessary, urinary sodium excretion can be reduced to virtually undetectable levels or increased dramatically.

Urinary sodium excretion is regulated by both intrarenal and extra-renal mechanisms. The most important determinant of renal sodium excretion is the volume status of the child; it is the effective intravascular volume that influences urinary sodium excretion. The effective intravascular volume is the volume status that is sensed by the body's regulatory mechanisms. Heart failure is a state of volume overload, but the effective intravascular volume is low because poor cardiac function prevents adequate perfusion of the kidneys and other organs. This fact explains the avid renal sodium retention that is often present in patients with heart failure.

Sodium resorption occurs throughout the nephron. Whereas the majority of filtered sodium is resorbed in the proximal tubule and the loop of Henle, the distal tubule and the collecting duct are the main sites for precise regulation of sodium balance. Approximately 65% of the filtered sodium is reclaimed in the proximal tubule, which is the major site for resorption of bicarbonate, glucose, phosphate, amino acids, and other substances that are filtered by the glomerulus. The transport of all these substances is linked to sodium resorption by cotransporters, or a sodium-hydrogen exchanger in the case of bicarbonate. This link is clinically important for bicarbonate and phosphate because their resorption parallels sodium resorption. In patients with **metabolic alkalosis and volume depletion**, correction of the metabolic alkalosis requires urinary loss of bicarbonate, but the volume depletion stimulates sodium and bicarbonate retention, preventing correction of the alkalosis. Volume expansion causes increased urinary losses of phosphate, even when there is phosphate depletion. Resorption of uric acid and urea occurs in the proximal tubule and increases when sodium retention increases. This arrangement accounts for the elevated uric acid and BUN measurements that often accompany dehydration, which is a stimulus for sodium retention in the proximal tubule. The cells of the proximal tubule are permeable to water; thus, water resorption in this segment parallels sodium resorption.

The loop of Henle is, in terms of absolute amount, the second most important site of sodium resorption along the nephron. The Na⁺,K⁺,2Cl⁻ cotransporter on the luminal side of the membrane reclaims filtered sodium and chloride, whereas most of the potassium is recycled back into the lumen. This is the transporter that is inhibited by furosemide and other loop diuretics, which are highly effective at increasing sodium excretion. The ascending limb of the loop of Henle is not permeable to water, permitting sodium retention without water. ADH stimulates sodium retention in this segment; this arrangement helps create a more hypertonic medulla, which maximizes water conservation when ADH acts in the medullary collecting duct. Because loop diuretics inhibit sodium retention in this segment, their use causes a less hypertonic medulla, permitting excretion of maximally concentrated urine in the presence of ADH.

Sodium retention in the distal tubule is mediated by the thiazide-sensitive Na⁺,Cl⁻ cotransporter. This segment of the nephron is relatively impermeable to water, and along with sodium and chloride retention, the distal tubule is important for delivery of fluid with a low sodium concentration to the collecting duct. This allows for excretion of water without sodium in patients who stop secreting ADH because of low plasma osmolality. Thiazide diuretics, by inhibiting sodium and chloride retention in this segment, prevent the excretion of water without electrolytes—partially explaining the severe hyponatremia that occasionally develops in patients receiving chronic thiazide diuretics.

The collecting duct, the final segment of the nephron, is important for the regulation of excretion of water, potassium, acid, and sodium. Even though the amount of sodium resorbed in this segment is less than in any other segment, this is the critical site for the regulation of sodium balance. Sodium resorption occurs via a sodium channel that is regulated by aldosterone. When these channels are open under the influence of aldosterone, almost all of the sodium can be resorbed. The uptake of sodium creates a negative charge in the lumen of the collecting duct, which facilitates the secretion of potassium and hydrogen ions. The potassium-sparing diuretics amiloride and triamterene block these sodium channels, and the inhibition of sodium uptake decreases potassium excretion. The potassium-sparing diuretic spironolactone blocks the binding of aldosterone to its receptor; thus, it indirectly decreases the activity of the sodium channels. The collecting duct is important for the regulation of water balance because it responds to ADH by inserting water channels that increase the permeability to water, and the hypertonicity of the renal medulla allows for maximal concentration of the urine.

The amount of sodium filtered at the glomerulus is directly proportional to the GFR. If sodium resorption in the nephron were constant, complete resorption of sodium with a small decrease in the GFR and significant renal sodium wasting with a small increase would result. This does not occur; however, because sodium resorption in the nephron is proportional to sodium delivery, a principle called *glomerular tubular balance*.

The renin-angiotensin system is an important regulator of renal sodium excretion. The juxtaglomerular apparatus produces renin in
response to decreased effective intravascular volume. Specific stimuli for renin release are decreased perfusion pressure in the afferent arteriole of the glomerulus, decreased delivery of sodium to the distal nephron, and β–adrenergic agonists, which increase in response to intravascular volume depletion. Renin, a proteolytic enzyme, cleaves angiotensinogen, producing angiotensin I. Angiotensin-converting enzyme converts angiotensin I into angiotensin II. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium resorption and stimulation of the adrenal gland to increase aldosterone secretion. Through its actions in the distal nephron—specifically, the late distal convoluted tubule and the collecting duct—aldosterone increases sodium resorption. Aldosterone also stimulates potassium excretion, increasing urinary losses. Along with decreasing urinary loss of sodium, angiotensin II acts as a vasconstrictor, which helps maintain adequate blood pressure in the presence of volume depletion.

Volume expansion stimulates the synthesis of atrial natriuretic peptide, which is produced by the atria in response to atrial wall distention. Along with increasing the GFR, atrial natriuretic peptide inhibits sodium resorption in the medullary portion of the collecting duct, facilitating an increase in urinary sodium excretion.

**Volume overload** occurs when sodium intake exceeds output. In children with kidney failure, there is an impaired ability to excrete sodium. This impairment tends to be proportional to the decrease in the GFR, although in some kidney diseases, such as renal dysplasia and juvenile nephronophthisis, damaged tubules cause significant sodium loss until the GFR is quite low. In general, as the GFR decreases, restriction of sodium intake becomes increasingly necessary. The GFR is low at birth, limiting a newborn's ability to excrete a sodium load. In other situations, there is a loss of the appropriate regulation of renal sodium excretion. This loss occurs in patients with excessive aldosterone, as is seen in primary hyperaldosteronism or renal artery stenosis, wherein excess renal production leads to high aldosterone levels. In acute glomerulonephritis, even without significantly reduced GFR, the normal intrarenal mechanisms that regulate sodium excretion malfunction, causing excessive renal retention of sodium and volume overload.

Renal retention of sodium occurs during volume depletion, but this appropriate response causes the severe excess in total body sodium that is present in heart failure, liver failure, nephrotic syndrome, and other causes of hypoalbuminemia. In these diseases, the effective intravascular volume is decreased, causing the kidney and the various regulatory systems to respond, leading to renal sodium retention and edema formation.

**Volume depletion** usually occurs when sodium losses exceed intake. The most common etiology in children is gastroenteritis. Excessive losses of sodium may also occur from the skin in children with burns, in sweat from patients with cystic fibrosis, or after vigorous exercise. Inadequate intake of sodium is uncommon except in neglect, in famine, or with an inappropriate choice of liquid diet in a child who cannot take solids. Urinary sodium wasting may occur in a range of renal diseases, from renal dysplasia to tubular disorders, such as Bartter syndrome. The neonate, especially if premature, has a mild impairment in the ability to conserve sodium. Iatrogenic renal sodium wasting takes place during diuretic therapy. Renal sodium loss occurs as a result of derangement in the normal regulatory systems. An absence of aldosterone, seen most commonly in children with congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, causes sodium wasting (see Chapter 576).

Isolated disorders of water balance can affect volume status and sodium balance. Because the cell membrane is permeable to water, changes in TBW influence both the extracellular volume and the intracellular volume. In isolated water loss, as occurs in diabetes insipidus, the impact is greater on the intracellular space because of its higher volume compared with the extracellular space. This is why, in comparison with other types of dehydration, hypernatremic dehydration has less impact on plasma volume; most of the fluid loss comes from the intracellular space. Yet, significant water loss eventually affects intravascular volume and will stimulate renal sodium retention, even if total body sodium content is normal. Similarly, with acute water intoxication or SIADH, there is an excess of TBW, but most is in the intracellular space. However, there is some effect on the intravascular volume, which causes renal excretion of sodium. Children with SIADH or water intoxication have high urine sodium concentrations, despite hyponatremia. This finding reinforces the concept that there are independent control systems for water and sodium, yet the 2 systems interact when pathophysiologic processes dictate, and control of effective intravascular volume always takes precedence over control of osmolality.

**55.3 Sodium**

Larry A. Greenbaum

**SODIUM METABOLISM**

**Body Content and Physiologic Function**

Sodium is the dominant cation of the ECF (see Fig. 55-3), and it is the principal determinant of extracellular osmolality. Sodium is therefore necessary for the maintenance of intravascular volume. Less than 3% of sodium is intracellular. More than 40% of total body sodium is in bone; the remainder is in the interstitial and intravascular spaces. The low intracellular sodium concentration, approximately 10 mEq/L, is maintained by Na+/K+-ATPase, which exchanges intracellular sodium for extracellular potassium.

**Intake**

A child's diet determines the amount of sodium ingested—a predominantly cultural determination in older children. An occasional child has salt craving because of an underlying salt-wasting renal disease or adrenal insufficiency. Children in the United States tend to have very high sodium intakes because their diets include a large amount of “junk” food or fast food. Infants receive sodium from breast milk (~7 mEq/L) and formula (7-13 mEq/L, for 20 calorie/oz formula).

Sodium is readily absorbed throughout the gastrointestinal tract. Mineralocorticoids increase sodium transport into the body, although this effect has limited clinical significance. The presence of glucose enhances sodium absorption owing to the presence of a cotransport system. This is the rationale for including sodium and glucose in oral rehydration solutions (see Chapter 340).

**Excretion**

Sodium excretion occurs in stool and sweat, but the kidney regulates sodium balance and is the principal site of sodium excretion. There is some sodium loss in stool, but it is minimal unless diarrhea is present. Normally, sweat has 5-40 mEq/L of sodium. Sweat sodium concentration is increased in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism. The higher sweat losses in these conditions may cause or contribute to sodium depletion.

Sodium is unique among electrolytes because water balance, not sodium balance, usually determines its concentration. When the sodium concentration increases, the resultant higher plasma osmolality causes increased thirst and increased secretion of ADH, which leads to renal conservation of water. Both of these mechanisms increase the water content of the body, and the sodium concentration returns to normal. During hyponatremia, the decrease in plasma osmolality stops ADH secretion, and consequent renal water excretion leads to an increase in the sodium concentration. Even though water balance is usually regulated by osmolality, volume depletion does stimulate thirst, ADH secretion, and renal conservation of water. Volume depletion takes precedence over osmolality; volume depletion stimulates ADH secretion, even if a patient has hyponatremia.

The excretion of sodium by the kidney is not regulated by the plasma osmolality. The patient's effective plasma volume determines the amount of sodium in the urine. This is mediated by a variety of regulatory systems, including the renin–angiotensin–aldosterone system and
Bibliography

intrinsic renal mechanisms. In hyponatremia or hypernatremia, the underlying pathophysiology determines the amount of urinary sodium, not the serum sodium concentration.

**HYPERNATREMIA**

Hypernatremia is a sodium concentration >145 mEq/L, although it is sometimes defined as >150 mEq/L. Mild hypernatremia is fairly common in children, especially among infants with gastroenteritis. Hypernatremia in hospitalized patients may be iatrogenic—caused by inadequate water administration or, less often, by excessive sodium administration. Moderate or severe hypernatremia has significant morbidity, including the result of underlying disease, the effects of hypernatremia on the brain, and the risks of overly rapid correction.

**Etiology and Pathophysiology**

There are 3 basic mechanisms of hypernatremia (Table 55-1). Sodium intoxication is frequently iatrogenic in a hospital setting as a result of correction of metabolic acidosis with sodium bicarbonate. Baking soda, a putative home remedy for upset stomach, is another source of sodium bicarbonate. Baking soda, often in a primiparous mother, can cause severe hypernatremic dehydration. Adipsia, the absence of thirst, is usually secondary to damage to the hypothalamus, such as from trauma, tumor, hydrocephalus, or histiocytosis. Primary adipsia is rare.

When hypernatremia occurs in conditions with deficits of sodium and water, the water deficit exceeds the sodium deficit. This occurs only if the patient is unable to ingest adequate water. Diarrhea results in depletion of both sodium and water. Because diarrhea is hypotonic—typical sodium concentration of 35-65 mEq/L—water losses exceed sodium losses, potentially leading to hypernatremia. Most children with gastroenteritis do not have hypernatremia because they drink enough hypotonic fluid to compensate for stool water losses (see Chapter 340). Fluids such as water, juice, and formula are more hypotonic than the stool losses, allowing correction of the water deficit and potentially even causing hyponatremia. Hypernatremia is most likely to occur in the child with diarrhea who has inadequate intake because of emesis, lack of access to water, or anorexia.

Osmotic agents, including mannitol and glucose in diabetes mellitus, cause excessive renal losses of water and sodium. Because the urine is hypotonic (sodium concentration of approximately 50 mEq/L) during an osmotic diuresis, water loss exceeds sodium loss and hypernatremia may occur if water intake is inadequate. Certain chronic kidney diseases, such as renal dysplasia and obstructive uropathy, are associated with tubular dysfunction, leading to excessive losses of sodium and water. Many children with such diseases have disproportionate water loss and are at risk for hypernatremic dehydration, especially if gastroenteritis supervenes. Similar mechanisms occur during the polyuric phase of acute tubular necrosis and after relief of urinary obstruction (postobstructive diuresis). Patients with either condition may have an osmotic diuresis from urinary losses of urea and an inability to conserve water because of tubular dysfunction.

**Clinical Manifestations**

Most children with hypernatremia are dehydrated and show the typical clinical signs and symptoms (see Chapter 57). Children with hypernatremic dehydration tend to have better preservation of intravascular volume because of the shift of water from the intracellular space to the extracellular space. This shift maintains blood pressure and urine output and allows hypernatremic infants to be less symptomatic initially and potentially to become more dehydrated before medical attention is sought. Breastfed infants with hypernatremia are often profoundly dehydrated, with failure to thrive. Probably because of intracellular water loss, the pinned abdominal skin of a dehydrated, hypernatremic infant has a "doughy" feel.

Hypernatremia, even without dehydration, causes central nervous system (CNS) symptoms that tend to parallel the degree of sodium elevation and the acuity of the increase. Patients are irritable, restless, weak, and lethargic. Some infants have a high-pitched cry and hyperventilation or apnea. Alert patients are very thirsty, even though nausea may be present. Hypernatremia may cause fever, although many patients have

an underlying process that contributes to the fever. Hypernatremia is associated with hyperglycemia and mild hypocalcemia; the mechanisms are unknown. Beyond the sequelae of dehydration, there is no clear direct effect of hypernatremia on other organs or tissues, except the brain.

**Brain hemorrhage** is the most devastating consequence of untreated hypernatremia. As the extracellular osmolality increases, water moves out of brain cells, leading to a decrease in brain volume. This decrease can result in tearing of intracerebral veins and bridging blood vessels as the brain moves away from the skull and the meninges. Patients may have subarachnoid, subdural, and parenchymal hemorrhages. Seizures and coma are possible sequelae of the hemorrhage, although seizures are more common during correction of hypernatremia. The cerebrospinal fluid protein is often elevated in infants with significant hypernatremia, probably owing to leakage from damaged blood vessels. Neonates, especially if premature, seem especially vulnerable to hypernatremia and excessive sodium intake. There is an association between rapid or hyperosmolar sodium bicarbonate administration and the development of intraventricular hemorrhages in neonates. Even though central pontine myelinolysis (CPM) is classically associated with overly rapid correction of hyponatremia, both CPM and extrapontine myelinolysis can occur in children with hypernatremia. Thrombotic complications occur in severe hypernatremic dehydration; they include stroke, dural sinus thrombosis, peripheral thrombosis, and renal vein thrombosis. This is secondary to dehydration and possibly hypercoagulability associated with hypernatremia.

**Diagnosis**

The etiology of hypernatremia is usually apparent from the history. Hypernatremia resulting from water loss occurs only if the patient does not have access to water or is unable to drink. In the absence of dehydration, it is important to ask about sodium intake. Children with excess sodium intake do not have signs of dehydration, unless another process is present. Severe sodium intoxication causes signs of volume overload, such as pulmonary edema and weight gain. Salt poisoning is associated with an elevated fractional excretion of sodium, whereas hypernatremic dehydration causes a low fractional excretion of sodium. In hyperaldosteronism, hypernatremia is usually mild or absent and is associated with edema, hypertension, hypokalemia, and metabolic alkalosis.

When there is isolated water loss, the signs of volume depletion are usually less severe initially because much of the loss is from the intracellular space. When pure water loss causes signs of dehydration, the hypernatremia and water deficit are usually severe. In the child with renal water loss, either central or nephrogenic diabetes insipidus, the urine is inappropriately dilute and urine volume is not low. The urine is maximally concentrated and urine volume is low if the losses are extrarenal or due to inadequate intake. With extrarenal causes of loss of water, the urine osmolality should be $>1,000$ mOsm/kg. When diabetes insipidus is suspected, the evaluation may include measurement of ADH and a water deprivation test, including a trial of desmopresin acetate (synthetic ADH analog) to differentiate between nephrogenic diabetes insipidus and central diabetes insipidus (see Chapters 530 and 558). A water-deprivation test is unnecessary if the patient has simultaneous documentation of hypernatremia and poorly concentrated urine (osmolality lower than that of plasma). In children with central diabetes insipidus, administration of desmopresin acetate increases the urine osmolality above the plasma osmolality, although maximum osmolality does not occur immediately because of the decreased osmolality of the renal medulla as a result of the chronic lack of ADH. In children with nephrogenic diabetes insipidus, there is no response to desmopresin acetate.

With combined sodium and water deficits, analysis of the urine differentiates between renal and nonrenal etiologies. When the losses are extrarenal, the kidney responds to volume depletion with low urine volume, concentrated urine, and sodium retention (urine sodium $<20$ mEq/L, fractional excretion of sodium $<1$%). With renal causes, the urine volume is not appropriately low, the urine is not maximally concentrated, and the urine sodium may be inappropriately elevated.

**Treatment**

As hypernatremia develops, the brain generates idiogenic osmoles to increase the intracellular osmolality and prevent the loss of brain water. This mechanism is not instantaneous and is most prominent when hypernatremia has developed gradually. If the serum sodium concentration is lowered rapidly, there is movement of water from the serum into the brain cells to equalize the osmolality in the 2 compartments (Fig. 55-4). The resultant brain swelling manifests as seizures or coma.

Because of the associated dangers, hypernatremia should not be corrected rapidly. The goal is to decrease the serum sodium by $<12$ mEq/L every 24 hr, a rate of 0.5 mEq/L/hr. The most important component of correcting moderate or severe hypernatremia is frequent monitoring of the serum sodium value so that fluid therapy can be adjusted to provide adequate correction, neither too slow nor too fast. If a child has seizures as a result of brain edema secondary to rapid correction, administration of hypotonic fluid should be stopped. An infusion of 3% saline can acutely increase the serum sodium, reversing the cerebral edema.

In the child with hypernatremic dehydration, as in any child with dehydration, the first priority is restoration of intravascular volume with isotonic fluid (see Chapter 57). Normal saline is preferable to lactated Ringer solution because the lower sodium concentration of the latter can cause the serum sodium to decrease too rapidly, especially if multiple fluid boluses are given. Repeated boluses of normal saline (10-20 mL/kg) may be required to treat hypotension, tachycardia, and signs of poor perfusion (peripheral pulses, capillary refill time) (see Chapters 57 and 70).

The sodium concentration of the deficit replacement fluid, the rate of fluid administration, and the presence of continued water losses determine the rate of decrease of the sodium concentration. The following formula is often cited for calculating the water deficit:

$$\text{Water deficit} = \frac{\text{Body weight} \times 0.6(1-145/\text{current sodium})}{20 \text{ mL/kg}}$$

This calculation is equivalent to 3-4 mL of water per kg for each 1 mEq that the current sodium level exceeds 145 mEq. The utility of such formulas has never been proven in clinical practice. Most patients with hypernatremic dehydration do well with a fluid sodium concentration of approximately half-normal saline, but with a fluid rate that is only 20-30% greater than maintenance fluid. Use of this...
concentration prevents excessive delivery of free water and too rapid a decrease in the serum sodium level. Patients with pure water loss may require a more hypotonic fluid (0.2 normal saline). Excessive water and sodium losses may also need to be replaced. If signs or symptoms of volume depletion develop, the patient receives additional boluses of isotonic saline. Monitoring of the rate of decrease of the serum sodium concentration permits adjustment in the rate and sodium concentration of the fluid that the patient is receiving, avoiding overly rapid correction of the hyponatremia (see Chapter 57 for additional details). Many patients with mild to moderate hypernatremic dehydration as a result of gastroenteritis can be managed with oral rehydration (see Chapter 340).

Acute, severe hypernatremia, usually secondary to sodium administration, can be corrected more rapidly because idiogenic osmoles have not had time to accumulate. This fact balances the high morbidity and mortality rates associated with hypernatremia with the dangers of overly rapid correction. When hypernatremia is severe and is caused by sodium intoxication, it may be impossible to administer enough water to correct the hypernatremia rapidly without worsening the volume overload. In this situation, dialysis allows for removal of the excess sodium, with the precise strategy dependent on the mode of dialysis. In less-severe cases, the addition of a loop diuretic increases the removal of excess sodium and water, decreasing the risk of volume overload. With sodium overload, hypernatremia is corrected with sodium-free intravenous fluid (5% dextrose in water).

Hyperglycemia from hypernatremia is not usually a problem and is not treated with insulin because the acute decrease in glucose may precipitate cerebral edema by lowering plasma osmolality. Rarely, the glucose concentration of intravenous fluids must be reduced (from 5% dextrose in water to 2.5% dextrose in water). The secondary hypocalcemia is treated as needed.

It is important to address the underlying cause of the hypernatremia, if possible. The child with central diabetes insipidus should receive desmopressin acetate. Because this treatment reduces renal excretion of water, excessive intake of water must consequently be avoided to prevent both overly rapid correction of the hypernatremia and the development of hyponatremia. Over the long-term, reduced sodium intake and the use of medications can somewhat ameliorate the water losses in nephrogenic diabetes insipidus (see Chapter 530). The daily water intake of a child who is receiving tube feeding may need to be increased to compensate for high losses. The patient with significant ongoing losses, such as through diarrhea, may need supplemental water and electrolytes (see Chapter 56). Sodium intake is reduced if it contributed to the hypernatremia.

**HYPONATREMIA**

Hyponatremia, a very common electrolyte abnormality in hospitalized patients, is a serum sodium level <135 mEq/L. Both total body sodium and TBW determine the serum sodium concentration. Hyponatremia exists when the ratio of water to sodium is increased. This condition can occur with low, normal, or high levels of body sodium. Similarly, body water can be low, normal, or high.

**Etiology and Pathophysiology**

Table 55-2 lists the causes of hyponatremia. Pseudohyponatremia is a laboratory artifact that is present when the plasma contains very high concentrations of protein (multiple myeloma, intravenous immunoglobulin infusion) or lipid (hypertriglyceridemia, hypercholesterolemia). It does not occur when a direct ion-selective electrode determines the sodium concentration in undiluted plasma, a technique that is used by arterial blood gas analyzers or point-of-care instruments. In true hyponatremia, the measured osmolality is low, whereas it is normal in pseudohyponatremia. Hyperosmolality, as may occur with hyperglycemia, causes a low serum sodium concentration because water moves down its osmotic gradient from the intracellular space into the extracellular space, diluting the sodium concentration. However, because the manifestations of hyponatremia are a result of the low plasma osmolality, patients with hyponatremia resulting from hyperosmolality do not have symptoms of hyponatremia. When the etiology of the hyperosmolality resolves, such as hyperglycemia in diabetes mellitus, water moves back into the cells and the sodium concentration rises to its "true" value. Mannitol or sucrose, a component of intravenous immunoglobulin preparations, may cause hyponatremia because of hyperosmolality.

Classification of hyponatremia is based on the patient’s volume status. In hypovolemic hyponatremia, the child has lost sodium from the body. The water balance may be positive or negative, but sodium loss has been higher than water loss. The pathogenesis of the

*Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.

hypoventilation is usually a combination of sodium loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and this fluid contains sodium. Most fluid that is lost has a lower sodium concentration than that of plasma. Viral diarrhea fluid has, on average, a sodium concentration of 50 mEq/L. Replacing diarrhea fluid, which has a sodium concentration of 50 mEq/L, with formula, which has only approximately 10 mEq/L of sodium, reduces the sodium concentration. Intravascular volume depletion interferes with renal water excretion, the body’s usual mechanism for preventing hyponatremia. The volume depletion stimulates ADH synthesis, resulting in renal water retention. Volume depletion also decreases the GFR and enhances water resorption in the proximal tubule, thereby reducing water delivery to the collecting duct.

Diabetes is a result of gastroenteritis in young children. Emesis causes hyponatremia if the patient takes in hypotonic fluid, either intravenously or enterally, despite the emesis. Most patients with emesis have either a normal sodium concentration or hyponatremia. Burns may cause massive losses of isotonic fluid and resultant volume depletion. Hyponatremia develops if the patient receives hypotonic fluid. Losses of sodium from sweat are especially high in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism, although high losses can occur simply in a hot climate. Third-space losses are isotonic and can cause significant volume depletion, leading to ADH production and water retention, which can cause hyponatremia if the patient receives hypotonic fluid. In diseases that cause volume depletion through extrarenal sodium loss, the urine sodium level should be low (<10 mEq/L) as part of the renal response to maintain the intravascular volume. The only exceptions are diseases that cause both extrarenal and renal sodium losses: adrenal insufficiency and pseudohypoaldosteronism.

Renal sodium loss may occur in a variety of situations. In some situations, the urine sodium concentration is >140 mEq/L; thus, hyponatremia may occur without any fluid intake. In many cases, the urine sodium level is less than the serum concentration; thus, the intake of hypotonic fluid is necessary for hyponatremia to develop. In diseased associated with urinary sodium loss, the urine sodium level is >20 mEq/L despite volume depletion. This may not be true if the urinary sodium loss is no longer occurring, as is frequently the case if diuretics are discontinued. Because loop diuretics prevent generation of a maximally hypertonic renal medulla, the patient can neither maximally dilute nor concentrate the urine. The inability to maximally retain water provides some protection against severe hyponatremia. The patient receiving thiazide diuretics can concentrate the urine and is at higher risk for severe hyponatremia. Osmotic agents, such as glucose during diabetic ketoacidosis, cause loss of both water and sodium. Urea accumulates during renal failure and then acts as an osmotic diuretic after relief of urinary tract obstruction and during the polyuric phase of acute tubular necrosis. Transient tubular damage in these conditions further impairs sodium conservation. The serum sodium concentration in these conditions depends on the sodium concentration of the fluid used to replace the losses. Hyponatremia develops when the fluid is hypotonic relative to the urinary losses.

Renal salt wasting occurs in hereditary kidney diseases, such as juvenile nephronophthisis and autosomal recessive polycystic kidney disease. Obstructive uropathy, most commonly a consequence of posterior urethral valves, produces salt wasting, but patients with the disease may also have hyponatremia as a result of impaired ability to concentrate urine and high water loss. Acquired tubulointerstitial nephritis, usually secondary to either medications or infections, may cause salt wasting, along with other evidence of tubular dysfunction. CNS injury may produce cerebral salt wasting, which is theoretically caused by the production of a natriuretic peptide that causes renal salt wasting. In type II renal tubular acidosis (RTA), usually associated with Fanconi syndrome (see Chapter 529.1), there is increased excretion of sodium and bicarbonate in the urine. Patients with Fanconi syndrome also have glycosuria, aminoaciduria, and hypophosphatemia because of renal phosphate wasting.

Aldosterone is necessary for renal sodium retention and for the excretion of potassium and acid. In congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, the block of aldosterone production results in hyponatremia, hyperkalemia, and metabolic acidosis. In pseudohypoaldosteronism, aldosterone levels are elevated, but there is no response because of either a defective sodium channel or a deficiency of aldosterone receptors. A lack of tubular response to aldosterone may occur in children with urinary tract obstruction, especially during an acute urinary tract infection.

In hypervolemic hyponatremia, there is an excess of TBW and sodium, although the increase in water is greater than the increase in sodium. In most of the conditions that cause hypervolemic hyponatremia, there is a decrease in the effective blood volume, resulting from third space fluid loss, vasodilation, or poor cardiac output. The regulatory systems sense a decrease in effective blood volume and attempt to retain water and sodium to correct the problem. ADH causes renal water retention, and the kidney, under the influence of aldosterone and other intrarenal mechanisms, retains sodium. The patient’s sodium concentration decreases because water intake exceeds sodium intake and ADH prevents the normal loss of excess water.

In these disorders, there is a low urine sodium concentration (<10 mEq/L) and an excess of both TBW and sodium. The only exception is in patients with renal failure and hyponatremia. These patients have an expanded intravascular volume, and hyponatremia can therefore appropriately suppress ADH production. Water cannot be excreted because very little urine is being made. Serum sodium is diluted through ingestion of water. Because of renal dysfunction, the urine sodium concentration may be elevated, but urine volume is so low that urine sodium excretion has not kept up with sodium intake, leading to sodium overload. The urine sodium concentration in renal failure varies. In patients with acute glomerulonephritis, because it does not affect the tubules, the urine sodium level is usually low, whereas in patients with acute tubular necrosis, it is elevated because of tubular dysfunction.

Patients with hyponatremia and no evidence of volume overload or volume depletion have euclidean hyponatremia. These patients typically have an excess of TBW and a slight decrease in total body sodium. Some of these patients have an increase in weight, implying that they are volume-overloaded. Nevertheless, from a clinical standpoint, they usually appear normal or have subtle signs of fluid overload.

In SIADH, the secretion of ADH is not inhibited by either low serum osmolality or expanded intravascular volume (see Chapter 559). The result is that the child with SIADH is unable to excrete water. This results in dilution of the serum sodium and hyponatremia. The expansion of the extracellular volume as a result of the retained water causes a mild increase in intravascular volume. The kidney increases sodium excretion in an effort to decrease intravascular volume to normal; thus, the patient has a mild decrease in body sodium. SIADH most commonly occurs with disorders of the CNS (infection, hemorrhage, trauma, tumor, thrombosis), but lung disease (infection, asthma, positive pressure ventilation) and malignant tumors (producing ADH) are other potential causes. A variety of medications may cause SIADH, including recreational use of 3,4-methylenedioxymethylamphetamines (MDMA, or “Ecstasy”), opiates, antiepileptic drugs (carbamazepine, oxcarbazepine, valproate), tricyclic antidepressants, vincristine, Cytoxan, and selective serotonin reuptake inhibitors. The diagnosis of SIADH is one of exclusion, because other causes of hyponatremia must be eliminated (Table 55-3). Because SIADH is a state of intravascular volume expansion, low serum uric acid and BUN levels are supportive of the diagnosis.

A rare gain-of-function mutation in the renal ADH receptor causes nephrogenic syndrome of inappropriate antidiuresis. Patients with this X-linked disorder appear to have SIADH but have undetectable levels of ADH.

Hyponatremia in hospitalized patients is frequently caused by inappropriate production of ADH and administration of hypotonic intravenous fluids. Causes of inappropriate ADH production include stress, medications such as narcotics or anesthetics, nausea, and respiratory illness. The synthetic analog of ADH, desmopressin acetate, causes...
water retention and may cause hyponatremia if fluid intake is not appropriately limited. The main uses of desmopressin acetate in children are for the management of central diabetes insipidus and of nocturnal enuresis.

**Excess water ingestion** can produce hyponatremia. In these cases, the sodium concentration decreases as a result of dilution. This decrease suppresses ADH secretion, and there is a marked water diuresis by the kidney. Hyponatremia develops only because the intake of water exceeds the kidney's ability to eliminate water. This condition is more likely to occur in infants because their lower GFR limits their ability to excrete water.

Hyponatremia may develop in infants <6 mo of age when caregivers offer water to their infants as a supplement, during hot weather, or when they run out of formula. Hyponatremia may result in transient seizures, hypothermia, and poor tone. With cessation of water intake, the hyponatremia rapidly corrects. Infants <6 mo of age should not be given water to drink; infants between 6 and 12 mo of age should not receive more than 1-2 ounces. If the infant appears thirsty, the parent should offer formula or breastfeed the child.

In some situations, the water intoxication causes acute hyponatremia and is a consequence of a massive acute water load. Examples of causes of this water load include infant swimming lessons, inappropriate use of hypotonic intravenous fluids, water enemas, and forced water intake as a form of child abuse. Chronic hyponatremia occurs in children who receive water, but limited sodium and protein. The minimum urine osmolality is approximately 50 mOsm/kg, the kidney can excrete 1 L of water only if there is enough solute ingested to produce 50 mOsm for urinary excretion. Because sodium and urea (a breakdown product of protein) are the principal urinary solutes, a lack of intake of sodium and protein prevents adequate water excretion. This occurs with the use of diluted formula or other inappropriate diets. Subsistence on beer, a poor source of sodium and protein, causes hyponatremia because of the inability to excrete the high water load ("beer potomania"). **Exercise-induced hyponatremia**, reported commonly during marathons, is caused by excessive water intake, salt losses from sweat, and secretion of ADH.

The pathogenesis of the hyponatremia in glucocorticoid deficiency is multifactorial, and includes increased ADH secretion. In hypoaldosteronism, there is an inappropriate retention of water by the kidney, but the precise mechanisms are not clearly elucidated.

**Clinical Manifestations**

Hyponatremia causes a decrease in the osmolality of the extracellular space. Because the intracellular space then has a higher osmolality, water moves from the extracellular space to the intracellular space to maintain osmotic equilibrium. The increase in intracellular water causes cells to swell. Although cell swelling is not problematic in most tissues, it is dangerous for the brain, which is confined by the skull. As brain cells swell, there is an increase in intracranial pressure, which impairs cerebral blood flow. Acute, severe hyponatremia can cause brainstem herniation and apnea; respiratory support is often necessary. Brain cell swelling is responsible for most of the symptoms of hyponatremia. Neurologic symptoms of hyponatremia include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. Patients may have thermoregulatory and Cheyne-Stokes respirations. Hyponatremia can cause muscle cramps and weakness; rhabdomyolysis can occur with water intoxication.

The symptoms of hyponatremia are mostly a result of the decrease in extracellular osmolality and the resulting movement of water down its osmotic gradient into the intracellular space. Brain swelling can be significantly obviated if the hyponatremia develops gradually, because brain cells adapt to the decreased extracellular osmolality by reducing intracellular osmolality. This reduction is achieved by excretion of the main intracellular ions (potassium and chloride) and a variety of small organic molecules. This process explains why the range of symptoms in hyponatremia is related to both the serum sodium level and its rate of decrease. A patient with chronic hyponatremia may have only subtle neurologic abnormalities with a serum sodium level of 110 mEq/L, but another patient may have seizures because of an acute decline in serum sodium level from 140 to 125 mEq/L.

**Diagnosis**

The history usually points to a likely etiology of the hyponatremia. Most patients with hyponatremia have a history of volume depletion. Diarrhea and diuretic use are very common causes of hyponatremia in children. A history of polyuria, perhaps with enuresis, and/or salt craving is present in children with primary kidney diseases or absence of aldosterone effect. Children may have signs or symptoms suggesting a diagnosis of hypothyroidism or adrenal insufficiency (see Chapters 565 and 575). Brain injury raises the possibility of SIADH or cerebral salt wasting, with the caveat that SIADH is much more likely. Liver disease, nephrotic syndrome, renal failure, or congestive heart failure may be acute or chronic. The history should include a review of the patient’s intake, both intravenous and enteral, with careful attention to the amounts of water, sodium, and protein.

The traditional first step in the diagnostic process is determination of the plasma osmolality. This is done because some patients with a low serum sodium value do not have low osmolality. The clinical effects of hyponatremia are secondary to the associated low osmolality. Without a low osmolality, there is no movement of water into the intracellular space. A patient with hyponatremia can have a low, normal, or high osmolality. A normal osmolality in combination with hyponatremia occurs in pseudohyponatremia. Children with elevation of serum glucose concentration or of another effective solute (mannitol) have a high plasma osmolality and hyponatremia. The presence of a low osmolality indicates "true" hyponatremia. Patients with low osmolality are at risk for neurologic symptoms and require further evaluation to determine the etiology of the hyponatremia.

In some situations, true hyponatremia is present despite a normal or elevated plasma osmolality. The presence of an ineffective osmole, most commonly urea, increases the plasma osmolality, but because the osmole has the same concentration in the intracellular space, it does not cause fluid to move into the extracellular space. There is no dilution of the serum sodium by water, and the sodium concentration remains unchanged if the ineffective osmole is eliminated. Most importantly, the ineffective osmole does not protect the brain from edema caused by hyponatremia. Hence, a patient may have symptoms of hyponatremia despite having a normal or increased osmolality because of uremia.

In patients with true hyponatremia, the next step in the diagnostic process is to clinically evaluate the volume status. Patients with hyponatremia can be hypovolemic, hypervolemic, or euvoolemic. The diagnosis of volume depletion relies on the usual findings with dehydration (see Chapter 57), although subtle volume depletion may not be clinically apparent. In a patient with subtle volume depletion, a fluid bolus results in a decrease in the urine osmolality and an increase in the serum sodium concentration. Children with hypervolemia are edematous on physical examination. They may have ascites, pulmonary edema, pleural effusion, or hypertension.

Hypovolemic hyponatremia can have renal or nonrenal causes. The urine sodium concentration is very useful in differentiating between renal and nonrenal causes. When the losses are nonrenal and the kidney is working properly, there is renal retention of sodium, a normal homeostatic response to volume depletion. Thus, the urinary sodium concentration is low, typically <10 mEq/L, although sodium conservation in neonates is less avid. When the kidney is the cause of the sodium loss, the urine sodium concentration is >20 mEq/L, reflecting the defect in renal sodium reabsorption. The interpretation of the urine sodium level is challenging with diuretic therapy because it is high when diuretics are being used but low after the diuretic effect is gone. This becomes an issue only when diuretic use is surreptitious. The urine sodium concentration is not useful if a metabolic alkalosis is present; the urine chloride concentration must be used instead (see Chapter 55.7).

Differentiating among the nonrenal causes of hypovolemic hyponatremia is usually facilitated by the history. Although the renal causes are more challenging to distinguish, a high serum potassium concentration is associated with disorders in which the sodium wasting is caused by absence of or ineffectiveness of aldosterone.

In the patient with hypervolemic hyponatremia, the urine sodium concentration is a helpful parameter. It is usually <10 mEq/L, except in the patient with renal failure.

**Treatment**

The management of hyponatremia is based on the pathophysiology of the specific etiology. The management of all causes requires judicious monitoring and avoidance of an overly quick normalization of the serum sodium concentration. A patient with severe symptoms (seizures), no matter the etiology, should be given a bolus of hypertonic saline to produce a small, rapid increase in serum sodium. Hypoxia worsens cerebral edema, and hyponatremia may cause hypoxia. Hence, pulse oximetry should be monitored, and hypoxia aggressively corrected.

With all causes of hyponatremia, it is important to avoid "overly rapid" correction. The reason is that rapid correction of hyponatremia may cause CPM. This syndrome, which occurs within several days of rapid correction of hyponatremia, produces neurologic symptoms, including confusion, agitation, flaccid or spastic quadriaparesis, and death. There are usually characteristic pathologic and radiologic changes in the brain, especially in the pons, but extrapontine lesions are quite common and may cause additional symptoms. Despite severe symptoms, full recovery does occur in some patients.

CPM is more common in patients who are treated for chronic hyponatremia than in those treated for acute hyponatremia. Presumably, this difference is based on the adaptation of brain cells to the hyponatremia. The reduced intracellular osmolality that is an adaptive mechanism for chronic hyponatremia makes brain cells susceptible to dehydration during rapid correction of the hyponatremia, and this may be the mechanism of CPM. Even though CPM is rare in pediatric patients, it is advisable to avoid correcting the serum sodium concentration by >12 mEq/L/24 hr or >18 mEq/L/48 hr. Desmopressin is a potential option if the serum sodium level is increasing too rapidly. This guideline does not apply to acute hyponatremia, as may occur with water intoxication, because the hyponatremia is more often symptomatic and there has not been time for the adaptive decrease in brain osmolality to occur. The consequences of brain edema in acute hyponatremia exceed the small risk of CPM.

Patients with hyponatremia can have severe neurologic symptoms, such as seizures and coma. The seizures associated with hyponatremia generally are poorly responsive to anticonvulsants. The child with hyponatremia and severe symptoms needs to receive treatment that will quickly reduce cerebral edema. This goal is best accomplished by increasing the extracellular osmolality so that water moves down its osmolar gradient from the intracellular space to the extracellular space.

Intravenous hypertonic saline rapidly increases serum sodium, and the effect on serum osmolality leads to a decrease in brain edema. Each mL/kg of 3% sodium chloride increases the serum sodium by approximately 1 mEq/L. A child with active symptoms often improves after receiving 4-6 mL/kg of 3% sodium chloride. The child with hypovolemic hyponatremia has a deficiency in sodium and may have a deficiency in water. The cornerstone of therapy is to replace the sodium deficit and any water deficit that is present. The first step in treating any dehydrated patient is to restore the intravascular volume with isotonic saline. Ultimately, complete restoration of intravascular volume suppresses ADH production, thereby permitting excretion of the excess water. Chapter 57 discusses the management of hyponatremic dehydration.

The management of hypervolemic hyponatremia is difficult. Patients with this disorder have an excess of both water and sodium. Administration of sodium leads to worsening volume overload and edema. In addition, the patients are retaining water and sodium because of their ineffective intravascular volume or renal insufficiency. The cornerstone of therapy is water and sodium restriction, because the patients have volume overload. Diuretics may help by causing excretion of both sodium and water. Vasopressin antagonists, by blocking the action of ADH and causing a water diuresis, are effective in correcting the hypervolemic hyponatremia caused by heart failure or cirrhosis.

Some patients with low albumin resulting from nephrotic syndrome have a better response to diuretics after an infusion of 25% albumin; the sodium concentration often normalizes as a result of expansion of the intravascular volume. A child with heart failure may have an increase in renal water and sodium excretion if there is an improvement in cardiac output. This improvement will "turn off" the regulatory hormones that are causing renal water (ADH) and sodium (aldosterone) retention. The patient with renal failure cannot respond to any of these therapies except fluid restriction. Insensible fluid losses eventually result in an increase in the sodium concentration as long as insensible and urinary losses are greater than intake. A more definitive approach in children with renal failure is to perform dialysis, which removes water and sodium.

In isovolumic hyponatremia, there is usually an excess of water and a mild sodium deficit. Therapy is directed at eliminating the excess water. The child with acute severe water intake loses water in the urine because ADH production is turned off as a result of the low plasma osmolality. Children may correct their hyponatremia spontaneously over 3-6 hr. For acute, symptomatic hyponatremia as a result of water intoxication, hypertonic saline may be needed to reverse cerebral edema. For chronic hyponatremia from poor solute intake, the child needs to receive an appropriate formula, and excess water intake should be eliminated.

Children with iatrogenic hyponatremia caused by the administration of hypertonic intravenous fluids should receive 3% saline if they are symptomatic. Subsequent management is dictated by the patient's volume status. The hypovolemic child should receive isotonic intravenous fluids. The child with nonphysiologic stimuli for ADH production should undergo fluid restriction. Prevention of this iatrogenic complication requires judicious use of intravenous fluids (see Chapter 56).

Specific hormone replacement is the cornerstone of therapy for the hyponatremia of hypothyroidism or cortisol deficiency. Correction of the underlying defect permits appropriate elimination of the excess water. SIA DH is a condition of excess water, with limited ability of the kidney to excrete water. The mainstay of its therapy is fluid restriction. Furosemide is effective in the patient with SIA DH and severe hyponatremia. Even in a patient with SIA DH, furosemide causes an increase in water and sodium excretion. The loss of sodium is somewhat counterproductive, but this sodium can be replaced with hypertonic saline. Because the patient has a net loss of water and the urinary losses of sodium have been replaced, there is an increase in the sodium concentration, but no significant increase in blood pressure. Vasopressin antagonists (conivaptan, lixivaptan, tolvaptan), which block the action of ADH and cause a water diuresis, are effective at correcting hyponatremic hyponatremia, but overly rapid correction is a potential complication.

Treatment of chronic SIA DH is challenging. Fluid restriction in children is difficult for nutritional and behavioral reasons. Other
options are long-term furosemide therapy with sodium supplementation, an oral vasopressin antagonist (tolvaptan), or oral urea.

### 55.4 Potassium

**Larry A. Greenbaum**

#### POTASSIUM METABOLISM

**Body Content and Physiologic Function**

The intracellular concentration of potassium, approximately 150 mEq/L, is much higher than the plasma concentration (see Fig. 55-3). The majority of body potassium is contained in muscle. As muscle mass increases, there is an increase in body potassium. There is thus an increase in body potassium during puberty, and it is more significant in males. The majority of extracellular potassium is in bone; <1% of total body potassium is in plasma.

Because most potassium is intracellular, the plasma concentration does not always reflect the total body potassium content. A variety of conditions alter the distribution of potassium between the intracellular and extracellular compartments. The Na⁺,K⁺-ATPase maintains the high intracellular potassium concentration by pumping sodium out of the cell and potassium into the cell. This activity balances the normal leak of potassium out of cells via potassium channels that is driven by the favorable chemical gradient. Insulin increases potassium movement into cells by activating the Na⁺,K⁺-ATPase. A decrease in pH drives potassium extracellularly; an increase in pH has the opposite effect. β-Adrenergic agonists stimulate the Na⁺,K⁺-ATPase, increasing cellular uptake of potassium. This increase is protective, in that hyperkalemia stimulates adrenomedullary release of catecholamines. α-Adrenergic agonists and exercise cause a net movement of potassium out of the intracellular space. An increase in plasma osmolality, as with mannitol infusion, leads to water movement out of the cells, and potassium follows as a result of solvent drag. The serum potassium concentration increases by approximately 0.6 mEq/L with each 10-mOsm rise in plasma osmolality.

The high intracellular concentration of potassium, the principal intracellular cation, is maintained via the Na⁺,K⁺-ATPase. The resulting chemical gradient is used to produce the resting membrane potential of cells. Potassium is necessary for the electrical responsiveness of nerve and muscle cells and for the contractility of cardiac, skeletal, and smooth muscle. The changes in membrane polarization that occur during muscle contraction or nerve conduction make these cells susceptible to changes in serum potassium levels. The ratio of intracellular to extracellular potassium determines the threshold for a cell to generate an action potential and the rate of cellular repolarization. The intracellular potassium concentration affects cellular enzymes. Potassium is necessary for maintaining cell volume because of its important contribution to intracellular osmolality.

**Intake**

Potassium is plentiful in food. Dietary consumption varies considerably, even though 1-2 mEq/kg is the recommended intake. The intestines normally absorb approximately 90% of ingested potassium. Most absorption occurs in the small intestine, whereas the colon exchanges body potassium for luminal sodium. Regulation of intestinal losses normally has a minimal role in maintaining potassium homeostasis, although renal failure, aldosterone, and glucocorticoids increase colonic secretion of potassium. The increase in intestinal losses in the setting of renal failure and hyperkalemia, which stimulates aldosterone production, is clinically significant, helping to protect against hyperkalemia.

**Excretion**

There is some loss of potassium in sweat, but it is normally minimal. The colon has the ability to eliminate some potassium. In addition, after an acute potassium load, much of the potassium, >40%, moves intracellularly, through the actions of epinephrine and insulin, which are produced in response to hyperkalemia. This process provides transient protection from hyperkalemia, but most ingested potassium is eventually excreted in the urine. The kidneys principally regulate long-term potassium balance, and they alter excretion in response to a variety of signals. Potassium is freely filtered at the glomerulus, but 90% is resorbed before the distal tubule and collecting duct, the principal sites of potassium regulation. The distal tubule and the collecting duct have the ability to absorb and secrete potassium. It is the amount of tubular secretion that regulates the amount of potassium that appears in the urine. The plasma potassium concentration directly influences secretion in the distal nephron. As the potassium concentration increases, secretion increases.

The principal hormone regulating potassium secretion is aldosterone, which is released by the adrenal cortex in response to increased plasma potassium. Its main site of action is the cortical collecting duct, where aldosterone stimulates sodium movement from the tubule into the cells. This movement creates a negative charge in the tubular lumen, facilitating potassium excretion. In addition, the increased intracellular sodium stimulates the basolateral Na⁺,K⁺-ATPase, causing more potassium to move into the cells lining the cortical collecting duct. Glucocorticoids, ADH, a high urinary flow rate, and high sodium delivery to the distal nephron also increase urinary potassium excretion. Potassium excretion is decreased by insulin, catecholamines, and urinary ammonia. Whereas ADH increases potassium secretion, it also causes water resorption, decreasing urinary flow. The net effect is that ADH has little overall impact on potassium balance. Alkalosis causes potassium to move into cells, including the cells lining the collecting duct. This movement increases potassium secretion, and because acidosis has the opposite effect, it decreases potassium secretion.

The kidney can dramatically vary potassium excretion in response to changes in intake. Normally, approximately 10-15% of the filtered load is excreted. In an adult, excretion of potassium can vary from 5-1,000 mEq/day.

#### HYPERKALEMIA

Hyperkalemia—because of the potential for lethal arrhythmias—is one of the most alarming electrolyte abnormalities.

**Etiology and Pathophysiology**

Three basic mechanisms cause hyperkalemia (Table 55-4). In the individual patient, the etiology is sometimes multifactorial.

**Spurious hyperkalemia or pseudohyperkalemia** is very common in children because of the difficulties in obtaining blood specimens. This laboratory result is usually caused by hemolysis during a heparinized or phlebotomy, but it can be the result of prolonged tourniquet application or fist clenching, either of which causes local potassium release from muscle.

The serum potassium level is normally 0.4 mEq/L higher than the plasma value, secondary to potassium release from cells during clot formation. This phenomenon is exaggerated with thrombocytosis because of potassium release from platelets. For every 100,000/m³ increase in the platelet count, the serum potassium level rises by approximately 0.15 mEq/L. This phenomenon also occurs with the marked white blood cell count elevations sometimes seen with leukemia. Elevated white blood cell counts, typically >200,000/m³, can cause a dramatic elevation in the serum potassium concentration. Analysis of a plasma sample usually provides an accurate result. It is important to analyze the sample promptly to avoid potassium release from cells, which occurs if the sample is stored in the cold, or cellular uptake of potassium and spurious hypokalemia, which occurs with storage of the sample at room temperature. Occasionally, heparin causes lysis of leukemic cells and a false elevation of the plasma sample; a blood gas syringe has less heparin and may provide a more accurate reading than a standard tube. There are rare genetic disorders causing leakage of potassium from red cells that may cause familial pseudohyperkalemia.
Bibliography

Because of the kidney’s ability to excrete potassium, it is unusual for excessive intake, by itself, to cause hyperkalemia. This condition can occur in a patient who is receiving large quantities of intravenous or oral potassium for excessive losses that are no longer present. Frequent or rapid blood transfusions can acutely increase the potassium level because of the potassium content of blood, which is variably elevated. Increased intake may precipitate hyperkalemia if there is an underlying defect in potassium excretion.

The intracellular space has a very high potassium concentration, so a shift of potassium from the intracellular space to the extracellular space can have a significant effect on the plasma potassium level. This shift occurs with metabolic acidoses, but the effect is minimal with an organic acid (lactic acidosis, ketoacidosis). A respiratory acidosis has less impact than a metabolic acidoses. Cell destruction, as seen with rhabdomyolysis, tumor lysis syndrome, tissue necrosis, or hemolysis, releases potassium into the extracellular milieu. The potassium released from red blood cells in internal bleeding, such as hematomas, is resorbed and enters the extracellular space.

Normal doses of succinylcholine or β-blockers and fluoride or digitalis intoxication all cause a shift of potassium out of the intracellular compartment. Succinylcholine should not be used during anesthesia in patients at risk for hyperkalemia. β-Blockers prevent the normal cellular uptake of potassium mediated by binding of β-agonists to the β-adrenergic receptors. Potassium release from muscle cells occurs during exercise, and levels can increase by 1-2 mEq/L with high activity. With an increased plasma osmolality, water moves from the intracellular space and potassium follows. This process occurs with hyperglycemia, although in nondiabetic patients, the resultant increase in insulin causes potassium to move intracellularly. In diabetic ketoacidosis, the absence of insulin causes potassium to leave the intracellular space, and the problem is compounded by the hyperosmolality. The effect of hyperosmolality causes a transcellular shift of potassium into the extracellular space after mannitol or hypertonic saline infusions. Malignant hyperthermia, which is triggered by some inhaled anesthetics, causes muscle release of potassium (see Chapter 611.2). Hyperkalemic periodic paralysis is an autosomal dominant disorder caused by a mutated sodium channel. It results in episodic cellular release of potassium and attacks of paralysis (see Chapter 611.1).

The kidneys excrete most of the daily potassium intake, so a decrease in kidney function can cause hyperkalemia. Newborn infants in general, and especially premature infants, have decreased kidney function at birth and thus are at increased risk for hyperkalemia despite an absence of intrinsic renal disease. Neonates also have decreased expression of potassium channels, further limiting potassium excretion.

A wide range of primary adrenal disorders, both hereditary and acquired, can cause decreased production of aldosterone, with secondary hyperkalemia (see Chapters 575 and 576). Patients with these disorders typically have metabolic acidosis and salt wasting with hypernatremia. Children with more subtle adrenal insufficiency may have electrolyte problems only during acute illnesses. The most common form of congenital adrenal hyperplasia, 21-hydroxylase deficiency, typically manifests in male infants as hyperkalemia, metabolic acidosis, hypernatremia, and volume depletion. Females with this disorder usually are diagnosed as newborns because of their ambiguous genitalia; treatment prevents the development of electrolyte problems.

Renin, via angiotensin II, stimulates aldosterone production. A deficiency in renin, a result of kidney damage, can lead to decreased aldosterone production. Hyporeninemia occurs in many kidney diseases, with some of the more common pediatric causes listed in Table 55-4. These patients typically have hyperkalemia and a metabolic acidosis, without hypernatremia. Some of these patients have impaired renal function, partially accounting for the hyperkalemia, but the impairment in potassium excretion is more extreme than expected for the degree of renal insufficiency.

A variety of renal tubular disorders impair renal excretion of potassium. Children with pseudohypoaldosteronism type 1 have hyperkalemia, metabolic acidosis, and salt wasting leading to hypernatremia and volume depletion; aldosterone values are elevated. In the autosomal recessive variant, there is a defect in the renal sodium channel that is normally activated by aldosterone. Patients with this variant have severe symptoms, beginning in infancy. Patients with the autosomal dominant form have a defect in the aldosterone receptor, and the disease is milder, often remitting in adulthood. Pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension), also called Gordon syndrome, is an autosomal dominant disorder characterized by hypertension caused by salt retention and impaired excretion of potassium and acid, leading to hyperkalemia and metabolic acidosis. Activating mutations in either WNK1 or WNK4, both serine-threonine kinases located in the distal nephron, cause Gordon syndrome. In the Bartter syndrome caused by

**NOTE:**

- Table 55-4 includes causes of hyperkalemia that may be due to factors affecting laboratory measurement. These include hemolysis, tissue ischemia, and other causes, which may affect the measured potassium level but are not directly related to hyperkalemia. OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).
mutations in the potassium channel ROMK (type 2 Bartter syndrome), there can be transient hyperkalemia in neonates, but hypokalemia subsequently develops (see Chapter 531).

Acquired renal tubular dysfunction, with an impaired ability to excrete potassium, occurs in a number of conditions. These disorders, all characterized by tubulointerstitial disease, are often associated with impaired acid secretion and a secondary metabolic acidosis. In some affected children, the metabolic acidosis is the dominant feature, although a high potassium intake may unmask the defect in potassium handling. The tubular dysfunction can cause renal salt wasting, potentially leading to hyponatremia. Because of the tubulointerstitial damage, these conditions may also cause hyperkalemia as a result of hyporeninemic hypoaldosteronism.

The risk of hyperkalemia resulting from medications is greatest in patients with underlying renal insufficiency. The predominant mechanism of medication-induced hyperkalemia is impaired renal excretion, although angiotensin-converting enzyme inhibitors may worsen hyperkalemia in anuric patients, probably by inhibiting gastrointestinal potassium loss, which is normally upregulated in renal insufficiency. The hyperkalemia caused by trimethoprim generally occurs only at the very high doses used to treat Pneumocystis jiroveci pneumonia in patients with AIDS. Potassium-sparing diuretics may easily cause hyperkalemia, especially because they are often used in patients who are receiving oral potassium supplements. Oral contraceptives containing drospirenone, which blocks the action of aldosterone, may cause hyperkalemia and should not be used in patients with decreased renal function.

**Clinical Manifestations**

The most important effects of hyperkalemia are a result of the role of potassium in membrane polarization. The cardiac conduction system is usually the dominant concern. Changes in the electrocardiogram (ECG) begin with peaking of the T waves. This is followed, as the potassium level increases, by ST-segment depression, an increased PR interval, flattening of the P wave, and widening of the QRS complex. This process can eventually progress to ventricular fibrillation. Asystole may also occur. Some patients have paresthesias, fasciculations, weakness, and even an ascending paralysis, but cardiac toxicity usually precedes these clinical symptoms, emphasizing the danger of assuming that an absence of symptoms implies an absence of danger. Chronic hyperkalemia is generally better tolerated than acute hyperkalemia.

**DIAGNOSIS**

The etiology of hyperkalemia is often readily apparent. Spurious hyperkalemia is very common in children, so obtaining a second potassium measurement is often appropriate. If there is a significant elevation of the white blood cell or platelet count, the second measurement should be performed on a plasma sample that is evaluated promptly. The history should initially focus on potassium intake, risk factors for transcellular shifts of potassium, medications that cause hyperkalemia, and the presence of signs of renal insufficiency, such as oliguria and edema. Initial laboratory evaluation should include creatinine, BUN, and assessment of the acid–base status. Many etiologies of hyperkalemia cause a metabolic acidosis; a metabolic acidosis worsens hyperkalemia through the transcellular shift of potassium out of cells. Renal insufficiency is a common cause of the combination of metabolic acidosis and hyperkalemia. This association is also seen in diseases associated with aldosterone insufficiency or aldosterone resistance. Children with absence of or ineffective aldosterone often have hyponatremia and volume depletion because of salt wasting. Genetic diseases, such as congenital adrenal hyperplasia and pseudohypoaldosteronism, usually manifest in infancy and should be strongly considered in the infant with hyperkalemia and metabolic acidosis, especially if hyponatremia is present. It is important to consider the various etiologies of a transcellular shift of potassium. In some of these disorders, the potassium level continues to increase, despite the elimination of all potassium intake, especially when there is concurrent renal insufficiency. This increase is potentially seen in tumor lysis syndrome, hemolysis, rhabdomyolysis, and other causes of cell death. All of these entities can cause concomitant hyperphosphatemia and hyperuricemia. Rhabdomyolysis produces an elevated creatinine phosphokinase (CPK) value and hypocalcemia, whereas children with hemolysis have hemoglobinuria and a decreasing hematocrit. For the child with diabetes, an elevated blood glucose value suggests a transcellular shift of potassium.

**Treatment**

The plasma potassium level, the ECG, and the risk of the problem worsening determine the aggressiveness of the therapeutic approach. High serum potassium levels and the presence of ECG changes require vigorous treatment. An additional source of concern is the patient in whom plasma potassium levels are rising despite minimal intake. This situation can happen if there is cellular release of potassium (tumor lysis syndrome), especially in the setting of diminished excretion (renal failure).

The first action in a child with a concerning elevation of plasma potassium is to stop all sources of additional potassium (oral, intravenous). Washed red blood cells can be used for patients who require blood transfusions. If the potassium level is >6.5 mEq/L, an ECG should be obtained to help assess the urgency of the situation. Peak T waves are the first sign of hyperkalemia followed by a prolonged PR interval and, when most severe, a prolonged QRS complex. Life-threatening ventricular arrhythmias may also develop. The treatment of hyperkalemia has 2 basic goals: (a) to stabilize the heart to prevent life-threatening arrhythmias and (b) to remove potassium from the body. The treatments that acutely prevent arrhythmias all have the advantage of working quickly (within minutes) but do not remove potassium from the body. Calcium stabilizes the cell membrane of heart cells, preventing arrhythmias. It is given intravenously over a few minutes, and its action is almost immediate. Calcium should be given over 30 min in a patient who is receiving digitalis, because otherwise the calcium may cause arrhythmias. Bicarbonate causes potassium to move intracellularly, lowering the plasma potassium level. It is most efficacious in a patient with a metabolic acidosis. Insulin causes potassium to move intracellularly but must be given with glucose to avoid hypoglycemia. The combination of insulin and glucose works within 30 min. Nebulized albuterol, by stimulation of β1-receptors, leads to rapid intracellular movement of potassium. This has the advantage of not requiring an intravenous route of administration, allowing it to be given concurrently with the other measures.

It is critical to begin measures that remove potassium from the body. In patients who are not anuric, a loop diuretic increases renal excretion of potassium. A high dose may be required in a patient with significant renal insufficiency. Sodium polystyrene sulfonate (Kayexalate) is an exchange resin that is given either rectally or orally. Sodium in the resin is then excreted from the body. Some patients require dialysis for acute potassium removal. Dialysis is often necessary if the patient has either severe renal failure or an especially high rate of endogenous potassium release, as is sometimes present with tumor lysis syndrome or rhabdomyolysis. Hemodialysis rapidly lowers plasma potassium levels. Peritoneal dialysis is not nearly as quick or reliable, but it is usually adequate as long as the acute problem can be managed with medications and the endogenous release of potassium is not high.

Long-term management of hyperkalemia includes reducing intake via dietary changes and eliminating or reducing medications that cause hyperkalemia (see Chapter 535). Some patients require medications to increase potassium excretion, such as sodium polystyrene sulfonate and loop or thiazide diuretics. Some infants with chronic renal failure may need to start dialysis to allow adequate caloric intake without hyperkalemia. It is unusual for an older child to require dialysis principally to control chronic hyperkalemia. The disorders that are caused by a deficiency in aldosterone respond to replacement therapy with fludrocortisone.

**HYPOKALEMIA**

Hypokalemia is common in children, with most cases related to gastroenteritis.
Etiology and Pathophysiology

There are 4 basic mechanisms of hypokalemia (Table 55-5). Spurious hypokalemia occurs in patients with leukemia and very elevated white blood cell counts if plasma for analysis is left at room temperature, permitting the white blood cells to take up potassium from the plasma. With a transcellular shift, there is no change in total body potassium, although there may be concomitant potassium depletion resulting from other factors. Decreased intake, extrarenal losses, and renal losses are all associated with total body potassium depletion.

Because the intracellular potassium concentration is much higher than the plasma level, a significant amount of potassium can move into cells without markedly changing the intracellular potassium concentration. Alkalosis is one of the more common causes of a transcellular shift. The effect is much greater with a metabolic alkalosis than with a respiratory alkalosis. The impact of exogenous insulin on potassium movement into the cells is substantial in patients with diabetic ketoacidosis. Endogenous insulin may be the cause when a patient is given a bolus of glucose. Both endogenous (epinephrine in stress) and exogenous (albuterol) β-adrenergic agonists stimulate cellular uptake of potassium. Theophylline overdose, barium intoxication, administration of cesium chloride (a homeopathic cancer remedy), and toluene intoxication from paint or glue sniffing can cause a transcellular shift hypokalemia, often with severe clinical manifestations. Children with hypokalemic periodic paralysis, a rare autosomal dominant disorder, have acute cellular uptake of potassium (see Chapter 611). Thyrotoxic periodic paralysis, which is more common in Asians, is an unusual initial manifestation of hyperthyroidism. Affected patients have dramatic hypokalemia as a result of a transcellular shift of potassium. Hypokalemia can occur during refeeding syndrome (see Chapter 338.8).

Inadequate potassium intake occurs in anorexia nervosa; accompanying bulimia and laxative or diuretic abuse exacerbates the potassium deficiency. Sweat losses of potassium can be significant during vigorous exercise in a hot climate. Associated volume depletion and hyperaldosteronism increase renal losses of potassium (discussed later). Diarrhea fluid has a high concentration of potassium, and hypokalemia as a result of diarrhea is usually associated with a metabolic acidosis resulting from stool losses of bicarbonate. In contrast, a normal acid-base balance or a mild metabolic alkalosis is seen with laxative abuse. Intake of sodium polystyrene sulfonate or ingestion of clay because of its high potassium and sodium content can cause a transcellular shift of potassium

*Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies. EAST, epilepsy, ataxia, sensorineural hearing loss, and tubulopathy; OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).
were cases of chloride deficiency resulting from infant formula deficiency in chloride, which caused a metabolic alkalosis with hypokalemia and low urine chloride levels. Current infant formula is not deficient in chloride. A similar mechanism occurs in cystic fibrosis because of chloride loss in sweat. In congenital chloride-losing diarrhea, an autosomal recessive disorder, there is a high stool loss of chloride, leading to metabolic alkalosis, an unusual sequela of diarrhea. Because of stool potassium losses, chloride deficiency, and metabolic alkalosis, patients with this disorder have hypokalemia. During respiratory alkalosis, there is renal compensation, with retention of bicarbonate and excretion of chloride. After the respiratory acidosis is corrected, the patients have chloride deficiency and posthypercapnic alkalosis with secondary hypokalemia. Patients with chloride deficiency, metabolic alkalosis, and hypokalemia have a urinary chloride level of <10 mEq/L. Loop and thiazide diuretics lead to hypokalemia, metabolic alkalosis, and chloride deficiency. During treatment, these patients have high urine chloride levels resulting from the effect of the diuretic. However, after the diuretics are discontinued, there is residual chloride deficiency, the urinary chloride level is appropriately low, and neither the hypokalemia nor the alkalosis resolves until the chloride deficiency is corrected.

The combination of metabolic alkalosis, hypokalemia, a high urine chloride level, and normal blood pressure is characteristic of Bartter syndrome, Gitelman syndrome, and current diuretic use. Patients with any of these conditions have high urinary losses of potassium and chloride, despite a state of relative volume depletion with secondary hyperaldosteronism. Bartter and Gitelman syndromes are autosomal recessive disorders caused by defects in tubular transporters (see Chapter 531). Bartter syndrome is usually associated with hypercalciuria, and often with nephrocalcinosis, whereas children with Gitelman syndrome have low urinary calcium losses but hypomagnesemia as a consequence of urinary magnesium losses. Some patients with Bartter syndrome have hypomagnesemia.

Some patients with hypoparathyroidism and hypokalemia caused by an activating mutation of the calcium-sensing receptor (autosomal dominant hypoparathyroidism) have hypokalemia, hypomagnesemia, and metabolic alkalosis. The reason is that activation of the calcium-sensing receptor in the loop of Henle impairs tubular resorption of sodium and chloride, causing volume depletion and secondary hyperaldosteronism. EAST syndrome, an autosomal recessive disorder caused by mutations in the gene for a potassium channel present in the kidney, inner ear, and brain, consists of epilepsy, ataxia, sensorineural hearing loss, and tubulopathy (hypokalemia, metabolic alkalosis, hypomagnesemia, and hypocalciuria).

In the presence of high aldosterone levels, there is urinary loss of potassium, hypokalemia, metabolic alkalosis, and an elevated urinary chloride level. Also, renal retention of sodium leads to hypertension.

Primary hyperaldosteronism caused by adenoma or hyperplasia is much less common in children than in adults (see Chapter 578). Glucocorticoid-remediable aldosteronism, an autosomal dominant disorder that leads to high levels of aldosterone, is often diagnosed in childhood, although hypokalemia is not always present.

Increased aldosterone levels may be secondary to increased renin production. Renal artery stenosis leads to hypertension from increased renin and secondary hyperaldosteronism. The increased aldosterone can cause hypokalemia and metabolic alkalosis, although most patients have normal electrolyte levels. Renin-producing tumors, which are extremely rare, can cause hypokalemia.

A variety of disorders cause hypertension and hypokalemia without increased aldosterone levels. Some are a result of increased levels of mineralocorticoids other than aldosterone. Such increases occur in 2 forms of congenital adrenal hyperplasia (see Chapter 576). In 11β-hydroxylase deficiency, which is associated with virilization, the value of 11-deoxycorticosterone is elevated, causing variable hypertension and hypokalemia. A similar mechanism, increased 11-deoxycorticosterone, occurs in 17α-hydroxylase deficiency, but patients with this disorder are more uniformly hypertensive and hypokalemic, and they have a defect in sex hormone production. Cushing syndrome, frequently associated with hypertension, less commonly causes metabolic alkalosis and hypokalemia. This is secondary to the mineralocorticoid activity of cortisol. In 11β-hydroxysteroid dehydrogenase deficiency, an autosomal recessive disorder, the enzymatic defect prevents the conversion of cortisol to cortisone in the kidney. Because cortisol binds to and activates the aldosterone receptor, children with this deficiency have all the features of excessive mineralocorticoids, including hypertension, hypokalemia, and metabolic alkalosis. Patients with this disorder, which is also called apparent mineralocorticoid excess, respond to spironolactone therapy, which blocks the mineralocorticoid receptor. An acquired form of 11β-hydroxysteroid dehydrogenase deficiency occurs from the ingestion of substances that inhibit this enzyme. A classic example is glycyrrhizic acid, which is found in natural licorice. Liddle syndrome is an autosomal dominant disorder that results from an activating mutation of the distal nephron sodium channel that is normally upregulated by aldosterone. Patients have the characteristics of hyperaldosteronism—hypertension, hypokalemia, and alkalosis—but low serum aldosterone levels. These patients respond to the potassium-sparing diuretics (triaterene and amiloride) that inhibit this sodium channel (see Chapter 531.3).

**Clinical Manifestations**

The heart and skeletal muscle are especially vulnerable to hypokalemia. ECG changes include a flattened T wave, a depressed ST segment, and the appearance of a U wave, which is located between the T wave (if still visible) and the P wave. Ventricular fibrillation and torsades de points may occur, although usually only in the context of underlying heart disease. Hypokalemia makes the heart especially susceptible to digitalis-induced arrhythmias, such as supraventricular tachycardia, ventricular tachycardia, and heart block (see Chapter 435).

The clinical consequences of hypokalemia in skeletal muscle include muscle weakness and cramps. Paralysis is a possible complication, generally only at potassium levels <2.5 mEq/L. It usually starts in the legs and moves to the arms. Respiratory paralysis may require mechanical ventilation. Some patients have rhabdomyolysis; the risk increases with exercise. Hypokalemia slows gastrointestinal motility. This effect manifests as constipation; with potassium levels <2.5 mEq/L, an ileus may occur. Hypokalemia impairs bladder function, potentially leading to urinary retention.

Hypokalemia causes polyuria and polydipsia by impairing urinary concentrating ability, which produces nephrogenic diabetes insipidus. Hypokalemia stimulates renal ammonia production, an effect that is clinically significant if hepatic failure is present, because the liver cannot metabolize the ammonia. Consequently, hypokalemia may worsen hepatic encephalopathy. Chronic hypokalemia may cause kidney damage, including interstitial nephritis and renal cysts.

**Diagnosis**

Most causes of hypokalemia are readily apparent from the history. It is important to review the child’s diet, gastrointestinal losses, and medications. Both emesis and diuretic use can be surreptitious. The presence of hypertension suggests excess mineralocorticoids. Concomitant electrolyte abnormalities are useful clues. The combination of hypokalemia and metabolic acidosis is characteristic of diarrhea and of distal and proximal RTA. A concurrent metabolic alkalosis is characteristic of emesis or nasogastric losses, aldosterone excess, use of diuretics, and Bartter and Gitelman syndromes. Figure 55-5 shows an approach to persistent hypokalemia.

If a clear etiology is not apparent, the measurement of urinary potassium distinguishes between renal and extrarenal losses. The kidneys should conserve potassium in the presence of extrarenal losses. Urinary potassium losses can be assessed with a 24-hr urine collection, a spot potassium : creatinine ratio, a fractional excretion of potassium, or calculation of the transtubular potassium gradient (TTKG), which is the most widely used approach in children:

\[
\text{TTKG} = \frac{[K]_{\text{urine}}}{[K]_{\text{plasma}} \times (\text{plasma osmolality/urine osmolality})}
\]

where \([K]_{\text{urine}} = \text{urine potassium concentration}\) and \([K]_{\text{plasma}} = \text{plasma potassium concentration}\).
Part VII  Fluid and Electrolyte Disorders

The urine osmolality must be greater than the serum osmolality for the result of this calculation to be valid. A TTKG > 4 in the presence of hypokalemia suggests excessive urinary losses of potassium. The urinary potassium excretion value can be misleading if the stimulus for renal loss, such as a diuretic, is no longer present.

**Treatment**

Factors that influence the treatment of hypokalemia include the potassium level, clinical symptoms, renal function, the presence of transcellular shifts of potassium, ongoing losses, and the patient’s ability to tolerate oral potassium. Severe, symptomatic hypokalemia requires aggressive treatment. Supplementation is more cautious if renal function is decreased because of the kidney’s limited ability to excrete excessive potassium. The plasma potassium level does not always provide an accurate estimation of the total body potassium deficit because there may be shifts of potassium from the intracellular space to the plasma. Clinically, such shifts occur most commonly with metabolic acidosis and the insulin deficiency of diabetic ketoacidosis; the plasma potassium measurement underestimates the degree of total body potassium depletion. When these problems are corrected, potassium moves into the intracellular space, so more potassium supplementation is required to correct the hypokalemia. Likewise, the presence of a transcellular shift of potassium into the cells indicates that the total body potassium depletion is less severe. In an isolated transcellular shift, as occurs in hypokalemic periodic paralysis, potassium supplementation should be used cautiously.
given the risk of hyperkalemia when the transcellular shift resolves. This caution is especially required in thyrotoxic periodic paralysis, which responds dramatically to propranolol, with correction of weakness and hypokalemia. Patients who have ongoing losses of potassium need correction of the deficit and replacement of the ongoing losses.

Because of the risk of hyperkalemia, intravenous potassium should be used very cautiously. Oral potassium is safer, albeit not as rapid in urgent situations. Liquid preparations are bitter tasting; microencapsulated or wax matrix formulations are less irritating than tablets to the gastric mucosa (oral dose: 2-4 mEq/kg/day with a maximum of 120-240 mEq/day in divided doses). The dose of intravenous potassium is 0.5-1.0 mEq/kg, usually given over 1 hr. The adult maximum dose is 40 mEq. Conservative dosing is generally preferred. Potassium chloride is the usual choice for supplementation, although the presence of concurrent electrolyte abnormalities may dictate other options.

Patients with acidosis and hypokalemia can receive potassium acetate or potassium citrate. If hypophosphatemia is present, then some of the potassium deficit can be replaced with potassium phosphate. It is sometimes possible to decrease ongoing losses of potassium. For patients with excessive urinary losses, potassium-sparing diuretics are effective, but they need to be used cautiously in patients with renal insufficiency. If hypokalemia, metabolic alkalosis, and volume depletion are present (with gastric losses), then restoration of intravascular volume with adequate sodium chloride will decrease urinary potassium losses. Correction of concurrent hypomagnesemia is important because hypomagnesemia may cause hypokalemia. Disease-specific therapy is effective in many of the genetic tubular disorders.

## 55.5 Magnesium
Larry A. Greenbaum

### MAGNESIUM METABOLISM

#### Body Content and Physiologic Function

Magnesium is the fourth most common cation in the body and the third most common intracellular cation (see Fig. 55-3). Between 50% and 60% of body magnesium is in bone, where it serves as a reservoir because 30% is exchangeable, allowing movement to the extracellular space. Most intracellular magnesium is bound to proteins; only approximately 25% is exchangeable. Because cells with higher metabolic rates have higher magnesium concentrations, most intracellular magnesium is present in muscle and liver.

The normal plasma magnesium concentration is 1.5-2.3 mg/dL (1.2-1.9 mEq/L; 0.62-0.94 mmol/L), with some variation among clinical laboratories. Infants have slightly higher plasma magnesium concentrations than older children and adults. Only 1% of body magnesium is extracellular (60% ionized; 15% complexed; 25% protein bound). In the United States, serum magnesium is reported as mg/dL (Table 55-6).

Values in the left-column unit are converted into the right-column unit via multiplying by the conversion factor (e.g., calcium of 10 mg/dL × 0.25 = 2.5 mmol/L). Division of the right-column unit by the conversion factor converts to the units of the left-column unit.

Magnesium is a necessary cofactor for hundreds of enzymes. It is important for membrane stabilization and nerve conduction. Adenosine triphosphate (ATP) and guanosine triphosphate need associated magnesium when they are used by adenosine triphosphatases, cyclases, and kinases.

#### Intake

Between 30% and 50% of dietary magnesium is absorbed. Good dietary sources include green vegetables, cereals, nuts, meats, and hard water, although many foods contain magnesium. Human milk contains approximately 35 mg/L of magnesium; formula contains 40-70 mg/L. The small intestine is the major site of magnesium absorption, but the regulation of magnesium absorption is poorly understood. There is passive absorption, which permits high absorption in the presence of excessive intake. It probably occurs via a paracellular mechanism. Absorption is diminished in the presence of substances that complex with magnesium (free fatty acids, fiber, phytate, phosphate, oxalate); increased intestinal motility and calcium also decrease magnesium absorption. Vitamin D and parathyroid hormone (PTH) may enhance absorption, although this effect is limited. Intestinal absorption does increase when intake is decreased, possibly via a saturable active transport system. If there is no oral intake of magnesium, obligatory secretory losses prevent the complete elimination of intestinal losses.

#### Excretion

Renal excretion is the principal regulator of magnesium balance. There is no defined hormonal regulatory system, although PTH may increase tubular resorption. Approximately 15% of resorption occurs in the proximal tubule, and 70% in the thick ascending limb (TAL) of the loop of Henle. Proximal resorption may be higher in neonates. High serum magnesium levels inhibit resorption in the TAL, suggesting that active transport is involved. Approximately 5-10% of filtered magnesium is resorbed in the distal tubule. Hypomagnesemia increases absorption in the TAL and the distal tubule.

#### Hypomagnesemia

Hypomagnesemia is relatively common in hospitalized patients, although most cases are asymptomatic. Detection requires a high index of suspicion because magnesium is not measured in most basic metabolic panels.

#### Etiology and Pathophysiology

Gastrointestinal and renal losses are the major causes of hypomagnesemia (Table 55-7). Diarrheal fluid contains up to 200 mg/L of magnesium; gastric contents have only approximately 15 mg/L, but high losses can cause depletion. Steatorrhea causes magnesium loss as a result of the formation of magnesium-lipid salts; restriction of dietary fat can decrease losses.

**Hypomagnesemia with secondary hypocalcemia**, a rare autosomal recessive disorder, is caused by decreased intestinal absorption of magnesium and renal magnesium wasting. Patients with this disorder have mutations in a gene (TRPM6) that is expressed in intestine and kidney. TRPM6 codes for a transient receptor potential cation channel. The patients have seizures, tetany, tremor, or restlessness at 2-8 wk of life as a result of severe hypomagnesemia (0.2-0.8 mg/dL) and secondary hypocalcemia.

Renal losses may occur because of medications that are direct tubular toxins. Amphotericin frequently causes significant magnesium wasting and is typically associated with other tubular defects (especially potassium wasting). Cisplatin produces dramatic renal magnesium losses. Diuretics affect tubular handling of magnesium. Loop diuretics cause a mild increase in magnesium excretion, and thiazide diuretics have even less effect. Chronic use of proton pump inhibitors may cause hypomagnesemia. Potassium-sparing diuretics reduce magnesium losses. Osmostic agents, such as mannitol, glucose in diabetes

Bibliography

Causes of Hypomagnesemia

**GASTROINTESTINAL DISORDERS**
- Diarrhea
- Nasogastric suction or emesis
- Inflammatory bowel disease
- Celiac disease
- Cystic fibrosis
- Intestinal lymphangiectasia
- Small bowel resection or bypass
- Pancreatitis
- Protein-calorie malnutrition
- Hypomagnesemia with secondary hypocalcemia (OMIM 602014)*

**RENNAL DISORDERS**
- Medications
  - Amphotericin
  - Cisplatin
  - Cyclosporin
  - Loop diuretics
  - Mannitol
  - Pentamidine
  - Proton pump inhibitors
  - Aminoglycosides
- Thiazide diuretics
- Epidermal growth factor receptor inhibitors
- Diabetes
- Acute tubular necrosis (recovery phase)
- Postobstructive nephropathy
- Chronic kidney diseases
- Intersitial nephritis
- Glomerulonephritis
- Post-renal transplantation
- Hypercalcemia
- Intravenous fluids
- Primary aldosteronism
- Genetic diseases
  - Gitelman syndrome (OMIM 263800)
  - Bartter syndrome (OMIM 607364/601678)
  - Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (OMIM 248250)
  - Familial hypomagnesemia with hypercalciuria, nephrocalcinosis, and severe ocular involvement (OMIM 248190)
  - Autosomal recessive renal magnesium wasting with normocalciuria (OMIM 611718)
  - Renal cysts and diabetes syndrome (OMIM 137920)
  - Autosomal dominant hypomagnesemia (OMIM 160120/613882/154020)
  - EAST syndrome (OMIM 612780)
  - Autosomal dominant hypoparathyroidism (OMIM 146200)
  - Mitochondrial disorders (OMIM 500005)

**MISCELLANEOUS CAUSES**
- Poor intake
- Hungry bone syndrome
- Insulin administration
- Pancreatitis
- Intrauterine growth retardation
- Infants of diabetic mothers
- Exchange transfusion

A number of rare genetic diseases cause renal magnesium loss. **Gitelman and Bartter syndromes**, both autosomal recessive disorders, are the most common entities (see Chapter 531). Gitelman syndrome, which is caused by a defect in the thiazide-sensitive Na⁺/Cl⁻ cotransporter in the distal tubule, is usually associated with hypomagnesemia. Hypomagnesemia occurs in a minority of patients with Bartter syndrome, which can be caused by mutations in multiple genes that are necessary for sodium and chloride reabsorption in the loop of Henle. In both disorders, there is hypokalemic metabolic alkalosis. Typically, hypomagnesemia is not severe and is asymptomatic, although tetany as a result of hypomagnesemia occasionally occurs.

**Familial hypomagnesemia with hypercalciuria and nephrocalcinosis** (Michelis-Castrillo syndrome), an autosomal recessive disorder, is caused by mutations in the gene for claudin 16 (paracellin-1), which is located in the tight junctions of the TAL of the loop of Henle. Patients with the disease have severe renal wasting of magnesium and calcium with secondary hypomagnesemia and nephrocalcinosis; serum calcium levels are normal. Chronic renal failure frequently occurs during childhood. Other features include kidney stones, urinary tract infections, hematuria, increased PTH levels, tetany, seizures, incomplete distal RTA, hyperuricemia, polycystic kidney disease, and polydipsia. Patients with familial hypomagnesemia with hypercalciuria, nephrocalcinosis, and severe ocular involvement have mutations in the gene for claudin 19.

**Autosomal recessive renal magnesium wasting with normocalciuria** is caused by mutations in the epidermal growth factor gene. Clinical manifestations include seizures, mild to moderate psychomotor retardation, and brisk tendon reflexes.

**Autosomal dominant renal magnesium wasting** is caused by mutations in a number of different genes. A dominant-negative mutation in the gene encoding the Na⁺,K⁺-adenosine triphosphatase γ subunit is associated with hypomagnesemia, increased urinary magnesium losses, hypercalciuria, and normocalcemia. Patients may present with seizures; most are asymptomatic, despite serum magnesium levels of 0.8-1.5 mg/dL. Mutations in CNNM2, which encodes a protein that mediates magnesium-sensitive sodium currents, cause isolated hypomagnesemia. A mutation in KCNA1, a gene that encodes a potassium channel, also causes an autosomal dominant form of hypomagnesemia; symptoms may be severe.

**Renal cysts and diabetes syndrome**, which is caused by mutations in the gene for hepatocyte nuclear factor-1β, is associated with hypomagnesemia, despite the frequent presence of renal insufficiency. The hypomagnesemia is usually mild but may cause symptomatic hypocalcemia. **EAST syndrome** is caused by mutations in a potassium channel, and patients with this autosomal recessive disorder have hypokalemia, metabolic alkalosis, and hypomagnesemia. **Autosomal dominant hypoparathyroidism** is caused by an activating mutation in the calcium-sensing receptor, which also senses magnesium levels in the kidney (see Chapter 571). The mutated receptor inappropriately perceives that magnesium and calcium levels are elevated, leading to urinary wasting of both cations. Hypomagnesemia, if present, is usually mild. A mutation in a mitochondrially encoded transfer RNA is associated with hypomagnesemia, hypertension, and hypercholesterolemia. Hypomagnesemia is occasionally present in children with other mitochondrial disorders.

Poor intake is an unusual cause of hypomagnesemia, although it can be seen in children who are hospitalized and receive only intravenous fluids without magnesium. In **hungry bone syndrome**, which most frequently occurs after parathyroidectomy in patients with hyperparathyroidism, magnesium moves into bone as a result of accelerated bone formation. These patients usually have hypocalcemia and hypophosphatemia via the same mechanism. A similar mechanism can occur during the refedding phase of protein-calorie malnutrition in children, with high magnesium use during cell growth depleting the patient’s limited reserves. Insulin therapy stimulates uptake of magnesium by cells, and in diabetic ketoacidosis, in which total body magnesium is low because of osmotic losses, hypomagnesemia frequently occurs. In **pancreatitis**, there is saponification of magnesium and calcium in necrotic fat, causing both hypomagnesemia and hypocalcemia.

*This disorder is also associated with renal magnesium wasting.

**EAST**, epilepsy, ataxia, sensorineural hearing loss, and tubulopathy,
Transient hypomagnesemia in newborns, which is sometimes idiopathic, is more commonly seen in infants of diabetic mothers, presumably as a result of maternal depletion from osmotic losses. Other maternal diseases that cause magnesium losses predispose infants to hypomagnesemia. Hypomagnesemia is more common in infants with intraperineal growth restriction. Hypomagnesemia may develop in newborn infants who require exchange transfusions because of magnesium removal by the citrate in banked blood.

Clinical Manifestations
Hypomagnesemia causes secondary hypocalcemia by impairing the release of PTH by the parathyroid gland and through blunting of the tissue response to PTH. Thus, hypomagnesemia is part of the differential diagnosis of hypocalcemia (see Chapter 57). It usually occurs only at magnesium levels <0.7 mg/dL. The dominant manifestations of hypomagnesemia are caused by hypocalcemia: tetany, presence of Chvostek and Trousseau signs, and seizures. However, with severe hypomagnesemia, these same signs and symptoms may be present despite normocalcemia. Persistent hypocalcemia caused by hypomagnesemia is a rare cause of rickets.

Many causes of hypomagnesemia also result in hypokalemia. Hypomagnesemia may produce renal potassium wasting and hypokalemia that corrects only with magnesium therapy. ECG changes with hypomagnesemia include flattening of the T wave and lengthening of the ST segment. Arrhythmias may occur, almost always in the setting of underlying heart disease.

Diagnosis
The etiology of hypomagnesemia is often readily apparent from the clinical situation. The child should be assessed for gastrointestinal disease, adequate intake, and kidney disease, with close attention paid to medications that may cause renal magnesium wasting. When the diagnosis is uncertain, an evaluation of urinary magnesium losses distinguishes between renal and nonrenal causes. The fractional excretion of magnesium (FE_Mg) is calculated via the following formula:

\[
FE_{Mg} = \frac{U_{Mg} \times P_{Cr}}{P_{Mg} \times U_{Cr}} \times 100
\]

where \( U_{Mg} \) is urinary magnesium concentration, \( P_{Cr} \) is plasma creatinine concentration, \( P_{Mg} \) is plasma magnesium concentration, and \( U_{Cr} \) is urinary magnesium concentration. The plasma magnesium concentration is multiplied by 0.7 because approximately 30% is bound to albumin and not filtered at the glomerulus.

The \( FE_{Mg} \) does not vary with age, but it does change according to the serum magnesium concentration. The \( FE_{Mg} \) ranges from 1-8% in children with normal magnesium levels. In the presence of hypomagnesemia as a result of extrarenal causes, it should be low because of renal conservation, typically <2%. The \( FE_{Mg} \) is inappropriately elevated in the setting of renal magnesium wasting; values are usually >4% and frequently >10%. The measurement should not be made during a magnesium infusion, because the acute increase in serum magnesium increases urinary magnesium. Other approaches for evaluating urinary magnesium losses include calculation of 24 hr urinary magnesium losses and of the ratio of urine magnesium:urine creatinine, both of which vary with age.

The genetic causes of renal magnesium loss are distinguished on the basis of the measurement of other serum and urinary electrolytes. Children with Gitelman and Bartter syndromes have hypokalemia and metabolic alkalosis.

Treatment
Severe hypomagnesemia is treated with parenteral magnesium. Magnesium sulfate is given at a dose of 25-50 mg/kg (0.05-0.1 mL/kg of a 50% solution; 2.5-5.0 mg/kg of elemental magnesium). It is administered as a slow intravenous infusion, although it may be given intramuscularly in neonates. The rate of intravenous infusion should be slowed if a patient experiences diaphoresis, flushing, or a warm sensation. The dose is often repeated every 6 hr (every 8-12 hr in neonates), for a total of 2-3 doses, before the plasma magnesium concentration is rechecked. Lower doses are used in children with renal insufficiency.

Long-term therapy is usually given orally. Preparations include magnesium gluconate (5.4 mg elemental magnesium/100 mg), magnesium oxide (60 mg elemental magnesium/100 mg), and magnesium sulfate (10 mg elemental magnesium/100 mg). There are sustained-released preparations, such as Slow-Mag (60 mg elemental magnesium/tablet) and Mag-Tab SR (84 mg elemental magnesium/tablet). Oral magnesium dosing should be divided to decrease cathartic side effects. Alternatively, oral magnesium are intramuscular injections and nighttime nasogastric infusion, both designed to minimize diarrhea. Magnesium supplementation must be used cautiously in the context of renal insufficiency.

HYPERMAGNESEMIA
Clinically significant hypermagnesemia is almost always secondary to excessive intake. It is unusual, except in neonates born to mothers who are receiving intravenous magnesium for preeclampsia or eclampsia (see Chapter 106).

Etiology and Pathophysiology
There is no feedback mechanism to prevent magnesium absorption from the gastrointestinal tract. Magnesium is present in high amounts in certain laxatives, enemas, cathartics used to treat drug overdoses, and antacids. It is also usually present in total parenteral nutrition, and neonates may receive high amounts transplacently if maternal levels are elevated. Usually the kidneys excrete excessive magnesium, but this ability is diminished in patients with chronic renal failure. In addition, neonates and young infants are vulnerable to excessive magnesium ingestion because of their reduced GFR. Most pediatric cases not related to maternal hypermagnesemia occur in infants as a result of excessive use of antacids or laxatives. Mild hypermagnesemia may occur in chronic renal failure, familial hypocalciuric hypercalcemia, diabetic ketoacidosis, lithium ingestion, milk-alkali syndrome, and tumor lysis syndrome. The hypermagnesemia in diabetic ketoacidosis occurs despite significant intracellular magnesium depletion as a result of urinary losses; hypomagnesemia often occurs after insulin treatment.

Clinical Manifestations
Symptoms usually do not appear until the plasma magnesium level is >4.5 mg/dL. Hypermagnesemia inhibits acetylcholine release at the neuromuscular junction, producing hypotonia, hyporeflexia, and weakness; paralysis occurs at high concentrations. The neuromuscular effects may be exacerbated by aminoglycoside antibiotics. Direct CNS depression causes lethargy and sleepiness; infants have a poor suck. Elevated magnesium values are associated with hypotension because of vascular dilation, which also causes flushing. Hypotension can be profound at higher concentrations from a direct effect on cardiac function. ECG changes include prolonged PR, QRS, and QT intervals. Severe hypermagnesemia (>15 mg/dL) causes complete heart block and cardiac arrest. Other manifestations of hypermagnesemia include nausea, vomiting, and hypocalcemia.

Diagnosis
Except for the case of the neonate with transplacental exposure, a high index of suspicion and a good history are necessary to make the diagnosis of hypermagnesemia. Prevention is essential; magnesium-containing compounds should be used judiciously in children with renal insufficiency.

Treatment
Most patients with normal renal function rapidly clear excessive magnesium. Intravenous hydration and loop diuretics can accelerate this process. In severe cases, especially in patients with underlying renal insufficiency, dialysis may be necessary. Hemodialysis works faster than peritoneal dialysis. Exchange transfusion is another option in newborn infants. Supportive care includes monitoring of cardiorespiratory status, provision of fluids, monitoring of electrolyte levels, and
Approximately 65% of plasma phosphorus is in phospholipids, but these compounds are insoluble in acid and are not measured by clinical laboratories. It is the phosphorus content of plasma phosphate that is determined. The result is reported as either phosphate or phosphorus, although even when the term phosphate is used, it is actually the phosphorus concentration that is measured and reported. The result is that the terms phosphate and phosphorus are often used interchangeably. The term phosphorus is preferred when one is referring to the plasma concentration. Conversion from the units used in the United States (mg/dL) to mmol/L is straightforward (see Table 55-6).

**PHOSPHORUS METABOLISM**

**Body Content and Physiologic Function**

Most phosphorus is in bone or is intracellular, with <1% in plasma. At a physiologic pH, there are monovalent and divalent forms of phosphate because the pK of these forms is 6.8. Approximately 80% is divalent, and the remainder is monovalent at a pH of 7.4. A small percentage of plasma phosphate, approximately 15%, is protein bound. The remainder can be filtered by the glomerulus, with most existing as free phosphate and a small percentage complexed with calcium, magnesium, or sodium. Phosphate is the most plentiful intracellular anion, although the majority is part of a larger compound (ATP).

More than that of any other electrolyte, the phosphate concentration varies with age (Table 55-8). The teleologic explanation for the high concentration during childhood is the need for phosphorus to facilitate growth. There is diurnal variation in the plasma phosphorus concentration, with the peak during sleep.

Phosphorus, as a component of ATP and other trinucleotides, is critical for cellular energy metabolism. It is necessary for cell signaling and nucleic acid synthesis, and it is a component of cell membranes and other structures. Along with calcium, phosphorus is necessary for skeletal mineralization. There is a significant need for a net positive phosphorus balance during growth, with the growing skeleton especially vulnerable to deficiency.

**Intake**

Phosphorus is readily available in food. Milk and milk products are the best sources of phosphorus; high concentrations are present in meat and fish. Vegetables have more phosphorus than fruits and grains. Gastrointestinal absorption of phosphorus is fairly proportional to intake, with approximately 65% of intake being absorbed, including a small amount that is secreted. Absorption, almost exclusively in the small intestine, occurs via a paracellular diffusive process and a vitamin D-regulated transcellular pathway. However, the impact of the change in phosphorus absorption caused by vitamin D is relatively small compared with the effect of variations in phosphorus intake.

**Excretion**

Despite the wide variation in phosphorus absorption dictated by oral intake, excretion matches intake, except for the needs for growth. The kidney regulates phosphorus balance, which is determined by intrarenal mechanisms and hormonal actions on the nephron.

Approximately 90% of plasma phosphate is filtered at the glomerulus, although there is some variation based on plasma phosphate and calcium concentrations. There is no significant secretion of phosphate along the nephron. Resorption of phosphate occurs mostly in the proximal tubule, although a small amount can be resorbed in the distal tubule. Normally, approximately 85% of the filtered load is resorbed.

A sodium-phosphate cotransporter mediates the uptake of phosphate into the cells of the proximal tubule.

The dietary phosphorus determines the amount of phosphate resorbed by the nephron. There are both acute and chronic changes in phosphate resorption that are based on intake. Many of these changes appear to be mediated by intrarenal mechanisms that are independent of regulatory hormones. Fibroblast growth factor-23 (FGF-23) inhibits renal resorption of phosphorus in the proximal tubule, and its level increases in the setting of hyperphosphatemia. FGF-23 also inhibits synthesis of calcitriol in the kidney by decreasing 1α-hydroxylase activity.

PTh, which is secreted in response to a low plasma calcium level, decreases resorption of phosphate, increasing the urinary phosphate level. This process appears to have a minimal effect during normal physiologic variation in PTh levels. However, it does have an impact in the setting of pathologic changes in PTh synthesis.

Low plasma phosphorus stimulates the 1α-hydroxylase in the kidney that converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol). Calcitriol increases intestinal absorption of phosphorus and is necessary for maximal renal resorption of phosphate. The effect of a change in calcitriol on urinary phosphate is significant only when the level of calcitriol was initially low, arguing against a role for calcitriol in nonpathologic conditions.

**HYPOPHOSPHATEMIA**

Because of the wide variation in normal plasma phosphorus levels, the definition of hypophosphatemia is age-dependent (see Table 55-8). The normal range reported by a laboratory may be based on adult normal values and, therefore, may be misleading in children. A serum phosphorus level of 3 mg/dL, a normal value in an adult, indicates clinically significant hypophosphatemia in an infant.

The plasma phosphorus level does not always reflect the total body stores because only 1% of phosphorus is extracellular. Thus, a child may have significant phosphorus deficiency despite a normal plasma phosphorus concentration. This situation is especially common in conditions in which there is a shift of phosphorus from the intracellular space.

**Etiology and Pathophysiology**

A variety of mechanisms cause hypophosphatemia (Table 55-9). A transcellular shift of phosphorus into cells occurs with processes that stimulate cellular usage of phosphorus (glycolysis). Usually, this shift causes only a minor, transient decrease in plasma phosphorus, but if intracellular phosphorus deficiency is present, the plasma phosphorus level can decrease significantly, producing symptoms of acute hypophosphatemia. Glucose infusion stimulates insulin release, leading to entry of glucose and phosphorus into the cells. Phosphorus is then used during glycolysis and other metabolic processes. A similar phenomenon can occur during the treatment of diabetic ketoacidosis, and patients with this disorder are typically phosphorus-depleted owing to urinary phosphorus losses. Refeeding of patients with protein-calorie malnutrition causes anabolism, which leads to significant cellular demand for phosphorus. The increased phosphorus uptake for incorporation into newly synthesized compounds containing phosphorus leads to hypophosphatemia, which can be severe and symptomatic. Refeeding hypophosphatemia occurs frequently during treatment of severe anorexia nervosa. It can occur during treatment of children with malnutrition from any cause, such as cystic fibrosis, Crohn

Bibliography
honesty. Very-low-birthweight infants have particularly rapid skeletal growth, and phosphorus deficiency and rickets may develop if they are fed human milk or formula for term infants. There is also a relative deficiency of calcium. The provision of additional calcium and phosphorus, using breast milk fortifier or special premature infant formula, prevents this complication. Phosphorus deficiency, sometimes with concomitant calcium and vitamin D deficiencies, occurs in infants who are not given enough milk or who receive a milk substitute that is nutritionally inadequate.

Antacids containing aluminum hydroxide, such as Maalox and Mylanta, bind dietary phosphorus and secreted phosphorus, preventing absorption. This process can cause phosphorus deficiency and rickets in growing children. A similar mechanism causes hypophosphatemia in patients who are overtreated for hyperphosphatemia with phosphorus binders. In children with kidney failure, the addition of dialysis to phosphorus binders increases the risk of iatrogenic hypophosphatemia in these normally hyperphosphatemic patients. This complication, which is more common in infants, can worsen renal osteodystrophy.

Excessive renal losses of phosphorus occur in a variety of inherited and acquired disorders. Because PTH inhibits the resorption of phosphorus in the proximal tubule, hyperparathyroidism causes hypophosphatemia (see Chapter 53). The dominant clinical manifestation, however, is hypercalcemia, and the hypophosphatemia is usually asymptomatic. The phosphorus level in hyperparathyroidism is not extremely low, and there is no continued loss of phosphorus because a new steady state is achieved at the lower plasma phosphorus level. Renal excretion, therefore, does not exceed intake over the long-term. There are occasional malignancies that produce PTH-related peptide, which has the same actions as PTH and causes hypophosphatemia and hypercalcemia.

A variety of diseases cause renal phosphate wasting, hypophosphatemia, and rickets resulting from excess FGF-23 (see Chapter 51). These disorders include X-linked hypophosphatemic rickets, tumors induced osteomalacia, autosomal dominant hypophosphatemic rickets, and autosomal recessive hypophosphatemic rickets. Heterozygous mutations in a phosphate transporter or a regulator of proximal rickets, and nephro lithiasis resulting from excess FGF-23 (see Chapter 51). The clinical sequelae are a result of the metabolic acidosis and hypophosphatemia. In children, an underlying genetic disease, most commonly cystinosis, often causes Fanconi syndrome, but it can be secondary to a variety of toxins and acquired diseases. Some patients have incomplete Fanconi syndrome, and phosphorus wasting may be one of the manifestations.

Dent disease, an X-linked disorder, can cause renal phosphorus wasting and hypophosphatemia, although the latter is not present in most cases. Other possible manifestations of Dent disease include tubular proteinuria, hypercalcuria, nephrolithiasis, rickets, and chronic renal failure. Dent disease may be secondary to mutations in a gene that encodes a chloride channel or the OCRL1 gene, which may also cause Lowe syndrome (see Chapter 529.1). Hypophosphatemic rickets with hypercalciuria is a rare disorder, principally described in kindreds from the Middle East. Mutations in a sodium-phosphate cotransporter cause hypophosphatemia in this disorder, and complications may include nephrolithiasis and osteoporosis; the disorder is autosomal dominant.

Metabolic acidosis inhibits resorption of phosphorus in the proximal tubule. In addition, metabolic acidosis causes a transcellular shift of phosphorus out of cells because of intracellular catabolism. This

released phosphorus is subsequently lost in the urine, leading to significant phosphorus depletion, even though the plasma phosphorus level may be normal. This classically occurs in diabetic ketoacidosis in which renal phosphorus loss is further increased by the osmotic diuresis. With correction of the metabolic acidosis and the administration of insulin, both of which cause a transcellular movement of phosphorus into the cells, there is a marked decrease in the plasma phosphorus level.

Volume expansion from any cause, such as hyperaldosteronism or SIADH, inhibits resorption of phosphorus in the proximal tubule. This effect also occurs with high rates of intravenous fluids. Thiazide and loop diuretics can increase renal phosphorus excretion, but the increase is seldom clinically significant. Glycosuria and glucocorticoids inhibit renal conservation of phosphorus. Hypophosphatemia is common after kidney transplantation as a result of urinary phosphorus losses. Possible explanations include preexisting secondary hyperparathyroidism from chronic renal failure, glucocorticoid therapy, and upregulation of FGF-23 before transplantation. The hypophosphatemia usually resolves in a few months.

Both acquired and genetic causes of vitamin D deficiency are associated with hypophosphatemia (see Chapter 51). The pathogenesis is multifactorial. Vitamin D deficiency, by impairing intestinal calcium absorption, causes secondary hyperparathyroidism that leads to increased urinary phosphorus wasting. An absence of vitamin D decreases intestinal absorption of phosphorus and directly decreases renal resorption of phosphorus. The dominant clinical manifestation is rickets, although some patients have muscle weakness that may be related to phosphorus deficiency.

Alcoholism is the most common cause of severe hypophosphatemia in adults. Fortunately, many of the risk factors that predispose adult alcoholics to hypophosphatemia are not usually present in adolescents (malnutrition, antacid abuse, recurrent episodes of diabetic ketoacidosis). Hypophosphatemia often occurs in sepsis, but the mechanism is not clear. Aggressive, protracted hemodialysis, as might be used for the treatment of methanol or ethylene glycol ingestion, can cause hypophosphatemia.

Clinical Manifestations
There are acute and chronic manifestations of hypophosphatemia. Rickets occurs in children with long-term phosphorus deficiency. The clinical features of rickets are described in Chapter 51.

Severe hypophosphatemia, typically at levels <1.0-1.5 mg/dL, may affect every organ in the body because phosphorus has a critical role in maintaining adequate cellular energy. Phosphorus is a component of ATP and is necessary for glycolysis. With inadequate phosphorus, red blood cell 2,3-diphosphoglycerate levels decrease, impairing release of oxygen to the tissues. Severe hypophosphatemia can cause hemolysis and dysfunction of white blood cells. Chronic hypophosphatemia causes proximal muscle weakness and atrophy. In the intensive care unit, phosphorus deficiency may slow weaning from mechanical ventilation or cause acute respiratory failure. Rhabdomyolysis is the most common complication of acute hypophosphatemia, usually in the setting of an acute transcellular shift of phosphorus into cells in a child with chronic phosphorus depletion (anorexia nervosa). The rhabdomyolysis is actually somewhat protective, in that there is cellular release of phosphorus. Other manifestations of severe hypophosphatemia include cardiac dysfunction and neurologic symptoms, such as tremor, paresthesia, ataxia, seizures, delirium, and coma.

Diagnosis
The history and basic laboratory evaluation often suggest the etiology of hypophosphatemia. The history should investigate nutrition, medications, and familial disease. Hypophosphatemia and rickets in an otherwise healthy young child suggests a genetic defect in renal phosphorus conservation, Fanconi syndrome, inappropriate use of antacids, poor nutrition, vitamin D deficiency, or a genetic defect in vitamin D metabolism. The patient with Fanconi syndrome usually has metabolic acidosis, glycosuria, aminoaciduria, and a low plasma uric acid level. Measurement of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, calcium, and PTH differentiates among the various vitamin D deficiency disorders and primary renal phosphate wasting (see Chapter 51). Hyperparathyroidism is easily distinguished by the presence of elevated plasma PTH and calcium values.

Treatment
The plasma phosphorus level, the presence of symptoms, the likelihood of chronic depletion, and the presence of ongoing losses dictate the approach to therapy. Mild hypophosphatemia does not require treatment unless the clinical situation suggests that chronic phosphorus depletion is present or that losses are ongoing. Oral phosphorus can cause diarrhea, so the doses should be divided. Intravenous therapy is effective in patients who have severe deficiency or who cannot tolerate oral medications. Intravenous phosphorus is available as either sodium phosphate or potassium phosphate, with the choice usually based on the patient's plasma potassium level. Starting doses are 0.08-0.16 mmol/kg over 6 hr. The oral preparations of phosphorus are available with various ratios of sodium and potassium. This is an important consideration because some patients may not tolerate the potassium load, whereas supplemental potassium may be helpful in some diseases, such as Fanconi syndrome and malnutrition. Oral maintenance dosages are 2-3 mmol/kg/day in divided doses.

Increasing dietary phosphorus is the only intervention needed in infants with inadequate intake. Other patients may also benefit from increased dietary phosphorus, usually from dairy products. Phosphorus-binding antacids should be discontinued in patients with hypophosphatemia. Certain diseases require specific therapy (see Chapter 51).

HYPERPHOSPHATEMIA

Etiology and Pathophysiology
Renal insufficiency is the most common cause of hyperphosphatemia, with the severity proportional to the degree of kidney impairment (see Chapter 535). This occurs because gastrointestinal absorption of the large dietary intake of phosphorus is unregulated, and the kidneys normally excrete this phosphorus. As renal function deteriorates, increased excretion of phosphorus is able to compensate. When kidney function is <30% of normal, hyperphosphatemia usually develops, although the time of its development may vary considerably according to dietary phosphorus absorption. Many of the other causes of hyperphosphatemia are more likely to develop in the setting of renal insufficiency (Table 55-10).

Cellular content of phosphorus is high relative to plasma phosphorus, and cell lysis can release substantial phosphorus. This is the etiology of hyperphosphatemia in tumor lysis syndrome, rhabdomyolysis, and acute hemolysis. These disorders cause concomitant potassium

release and the risk of hyperkalemia. Additional features of tumor lysis and rhabdomyolysis are hyperuricemia and hypocalcemia, whereas indirect hyperbilirubinemia and elevated lactate dehydrogenase values are often present with hemolysis. An elevated CPK level is suggestive of rhabdomyolysis. During lactic acidosis or diabetic ketoacidosis, usage of phosphorus by cells decreases, and phosphorus shifts into the extracellular space. This problem reverses when the underlying problem is corrected, and especially with diabetic ketoacidosis, patients subsequently become hypophosphatemic as a result of previous renal phosphorus loss.

Excessive intake of phosphorus is especially dangerous in children with renal insufficiency. Neonates are at risk because renal function is normally reduced during the 1st few months of life. In addition, they may erroneously be given doses of phosphorus that are meant for an older child or adult. In infants fed cow’s milk, which has higher phosphorus content than breast milk or formula, hyperphosphatemia may develop. *Fleet Enema* has a high amount of phosphorus that can be absorbed, especially in the patient with an ileus. Infants and children with Hirschsprung disease are especially vulnerable. There is often associated hypernatremia owing to sodium absorption and water loss from diarrhea. Sodium phosphorus laxatives may cause hyperphosphatemia if the dose is excessive or if renal insufficiency is present. Hyperphosphatemia occurs in children who receive overly aggressive treatment for hypophosphatemia. Vitamin D intoxication causes excessive gastrointestinal absorption of both calcium and phosphorus, and the suppression of PTH by hypercalcemia decreases renal phosphorus excretion.

The absence of PTH in *pseudohypoparathyroidism* or PTH responsiveness in *pseudohypoparathyroidism* causes hyperphosphatemia because of increased resorption of phosphorus in the proximal tubule of the kidney (see Chapters 571 and 572). The associated hypocalcemia is responsible for the clinical symptoms. The hyperphosphatemia in hyperparathyroidism or acromegaly is usually minor. It is secondary to increased resorption of phosphorus in the proximal tubule from the actions of thyroxine or growth hormone. Excessive thyroxine can also cause bone resorption, which may contribute to the hyperphosphatemia and cause hypercalcemia. Patients with *familial tumoral calcinosis*, a rare autosomal recessive disorder, have hyperphosphatemia as a result of decreased renal phosphate excretion and heterotopic calcifications. The disease may be secondary to mutations in the genes for a glycosyltransferase, the phospha tin FGF-23, or the gene for Klotho, which encodes the coreceptor for FGF-23.

**Clinical Manifestations**

The primary clinical consequences of hyperphosphatemia are hypocalcemia and systemic calcification. The hypocalcemia is probably due to decreased deposition of calcium-phosphorus salt, inhibition of 1,25-dihydroxyvitamin D production, and decreased bone resorption. Symptomatic hypocalcemia is most likely to occur when the phosphorus level increases rapidly or when diseases predisposing to hypocalcemia are present (chronic renal failure, rhabdomyolysis). Systemic calcification occurs because the solubility of phosphorus and calcium in the plasma is exceeded. This is believed to happen when plasma calcium × plasma phosphorus, both measured in mg/dL, is >70. Clinically, this condition is often apparent in the conjunctiva, where it manifests as a foreign-body feeling, erythema, and injection. More ominous manifestations are hypoxia from pulmonary calcification and renal failure from nephrocalcinosis.

**Diagnosis**

Plasma creatinine and BUN levels should be assessed in any patient with hyperphosphatemia. The history should focus on intake of phosphorus and the presence of chronic diseases that may cause hyperphosphatemia. Measurement of potassium, uric acid, calcium, lactate dehydrogenase, bilirubin, hemoglobin, and CPK may be indicated if rhabdomyolysis, tumor lysis, or hemolysis is suspected. With mild hyperphosphatemia and significant hypocalcemia, measurement of the serum PTH level distinguishes between hypoparathyroidism and pseudohypoparathyroidism.

**Treatment**

The treatment of acute hyperphosphatemia depends on its severity and etiology. Mild hyperphosphatemia in a patient with reasonable renal function spontaneously resolves; the resolution can be accelerated by dietary phosphorus restriction. If kidney function is not impaired, then intravenous fluids can enhance renal phosphorus excretion. For more significant hyperphosphatemia or a situation such as tumor lysis or rhabdomyolysis, in which endogenous phosphorus generation is likely to continue, addition of an oral phosphorus binder prevents absorption of dietary phosphorus and can remove phosphorus from the body by binding what is normally secreted and absorbed by the gastrointestinal tract. Phosphorus binders are most effective when given with food.

Binders containing aluminum hydroxide are especially efficient, but calcium carbonate is an effective alternative and may be preferred if there is a need to treat concomitant hypocalcemia. Preservation of renal function, for example with high urine flow in rhabdomyolysis or tumor lysis, is an important adjunct because it will permit continued excretion of phosphorus. If the hyperphosphatemia is not responding to conservative management, especially if renal insufficiency is supervening, then dialysis may be necessary to increase phosphorus removal.

Dietary phosphorus restriction is necessary for diseases causing chronic hyperphosphatemia. However, such diets are often difficult to follow, given the abundance of phosphorus in a variety of foods. Dietary restriction is often sufficient in conditions such as hypoparathyroidism and mild renal insufficiency. For more problematic hyperphosphatemia, such as with moderate renal insufficiency and end-stage renal disease, phosphorus binders are usually necessary. They include calcium carbonate, calcium acetate, sevelamer, and lanthanum. Aluminum-containing phosphorus binders are no longer used in chronic renal insufficiency because of the risk of aluminum toxicity. Dialysis directly removes phosphorus from the blood in patients with end-stage renal disease, but it is only an adjunct to dietary restriction and phosphorus binders, in that elimination of phosphorus by dialysis is not efficient enough to keep up with normal dietary intake.

55.7 Acid–Base Balance

Larry A. Greenbaum

**ACID–BASE PHYSIOLOGY**

**Introduction and Terminology**

Chronic, mild derangements in acid–base status may interfere with normal growth and development, whereas acute, severe changes in pH can be fatal. Control of acid–base balance depends on the kidneys, the lungs, and intracellular and extracellular buffers.

A normal pH is 7.35-7.45. There is an inverse relationship between the pH and the hydrogen ion concentration. At a pH of 7.40, the hydrogen ion concentration is 40 mmol/L. A normal serum sodium concentration, 140 mEq/L, is 1 million times higher. Maintaining a normal pH is necessary because hydrogen ions are highly reactive and are especially likely to combine with proteins, altering their function.

An acid is a substance that releases ("donates") a hydrogen ion (H⁺). A base is a substance that accepts a hydrogen ion. An acid (HA) can dissociate into a hydrogen ion and a conjugate base (A⁻), as follows:

\[
HA \leftrightarrow H^+ + A^- 
\]

A strong acid is highly dissociated, so in this reaction, there is little HA. A weak acid is poorly dissociated; not all of the hydrogen ions are released from HA. A⁻ acts as a base when the reaction moves to the left. These reactions are in equilibrium. When HA is added to the system, there is dissociation of some HA until the concentrations of H⁺ and A⁻ increase enough that a new equilibrium is reached. Addition of hydrogen ions causes a decrease in A⁻ and an increase in HA. Addition of A⁻ causes a decrease in hydrogen ions and an increase in HA.

**Buffers** are substances that attenuate the change in pH that occurs when acids or bases are added to the body. Given the extremely low
Chapter 55  Electrolyte and Acid-Base Disorders

Bibliography
Carpenter TO: The expanding family of hypophosphatemic syndromes, J Bone Miner Metab 30:1–9, 2012.
concentration of hydrogen ions in the body at physiologic pH, without buffers a small amount of hydrogen ions could cause a dramatic decline in the pH. Buffers prevent the decrease in pH by binding the added hydrogen ions, as follows:

\[ A^- + H^+ \rightarrow HA \]

The increase in hydrogen ion concentration drives this reaction to the right. Similarly, when base is added to the body, buffers prevent the pH from increasing by releasing hydrogen ions, as follows:

\[ HA \rightarrow A^- + H^+ \]

The best buffers are weak acids and bases. This is because a buffer works best when it is 50% dissociated (half HA and half A⁻). The pH at which a buffer is 50% dissociated is its pK (ionization constant of acid). The best physiologic buffers have a pK close to 7.40. The concentration of a buffer and its pK determine the buffer’s effectiveness (buffering capacity). When the pH is lower than the pK of a buffer, there is more HA than A⁻. When the pH is higher than the pK, there is more A⁻ than HA.

**Physiologic Buffers**

The bicarbonate and nonbicarbonate buffers protect the body against major changes in pH. The bicarbonate buffer system is routinely monitored clinically. The bicarbonate buffer system is based on the relationship between carbon dioxide (CO₂) and bicarbonate (HCO₃⁻):

\[ \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}^+ + \text{HCO}_3^- \]

Carbon dioxide acts as an acid in that, after combining with water, it releases a hydrogen ion: bicarbonate acts as its conjugate base in that it accepts a hydrogen ion. The pK of this reaction is 6.1. The Henderson-Hasselbalch equation expresses the relationship among pH, pK, and the concentrations of an acid and its conjugate base. This relationship is valid for any buffer. The Henderson-Hasselbalch equation for bicarbonate and carbon dioxide is as follows:

\[ \text{pH} = 6.1 + \log[\text{HCO}_3^-]/[\text{CO}_2] \]

The Henderson-Hasselbalch equation for the bicarbonate buffer system has 3 variables: pH, [HCO₃⁻], and [CO₂]. Thus, if any 2 of these variables are known, it is possible to calculate the third. When one is using the Henderson-Hasselbalch equation, it is important that carbon dioxide and bicarbonate have the same units. Carbon dioxide is reported clinically as mm Hg and must be multiplied by its solubility constant, 0.03 mmol/L/mm Hg, before the Henderson-Hasselbalch equation can be used. Mathematical manipulation of the Henderson-Hasselbalch equation produces the following relationship:

\[ [\text{H}^+] = 24 \times \text{PCO}_2/[\text{HCO}_3^-] \]

At a normal hydrogen ion concentration of 40 nmol (pH 7.40), the partial pressure of carbon dioxide (PCO₂), which is expressed as mm Hg in this equation, is 40 when the bicarbonate concentration is 24 mEq/L. This equation emphasizes that the hydrogen ion concentration, and hence pH, can be determined by the ratio of PCO₂ and the bicarbonate concentration.

The bicarbonate buffer system is very effective as a result of the high concentration of bicarbonate in the body (24 mEq/L) and the fact that it is an open system. The remaining body buffers are in a closed system. The bicarbonate buffer system is an open system because the lungs increase carbon dioxide excretion when the blood carbon dioxide concentration increases. When acid is added to the body, the following reaction occurs:

\[ \text{H}^+ + \text{HCO}_3^- \rightarrow \text{CO}_2 + \text{H}_2\text{O} \]

In a closed system, the CO₂ would increase. The higher CO₂ concentration would lead to an increase in the reverse reaction:

\[ \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}^+ + \text{HCO}_3^- \]

This would increase the concentration of hydrogen ions, limiting the buffering capacity of bicarbonate. However, because the lungs excrete the excess carbon dioxide, the reverse reaction does not increase; this fact enhances the buffering capacity of bicarbonate. The same principle holds with the addition of base, because the lungs decrease carbon dioxide excretion and prevent the level of carbon dioxide from falling. The lack of change in carbon dioxide concentration dramatically increases the buffering capacity of bicarbonate.

The nonbicarbonate buffers include proteins, phosphate, and bone. Protein buffers consist of extracellular proteins, mostly albumin and intracellular proteins, including hemoglobin. Proteins are effective buffers, largely because of the presence of the amino acid histidine, which has a side chain that can bind or release hydrogen ions. The pK of histidine varies slightly, depending on its position in the protein molecule, but its average pK is approximately 6.5. This is close enough to a normal pH (7.4) to make histidine an effective buffer. Hemoglobin and albumin have 34 and 16 histidine molecules, respectively.

Phosphate can bind up to 3 hydrogen molecules, so it can exist as PO₄³⁻, HPO₄²⁻, H₂PO₄⁻, or H₃PO₄. However, at a physiologic pH, most phosphate exists as either HPO₄²⁻ or H₂PO₄⁻. H₂PO₄⁻ is an acid, and HPO₄²⁻ is its conjugate base:

\[ \text{H}_2\text{PO}_4^- \leftrightarrow \text{H}^+ + \text{HPO}_4^{2-} \]

The pK of this reaction is 6.8, making phosphate an effective buffer. The concentration of phosphate in the extracellular space is relatively low, limiting the overall buffering capacity of phosphate; it is less important than albumin. However, phosphate is found at a much higher concentration in the urine, where it is an important buffer. In the intracellular space, most phosphate is covalently bound to organic molecules (ATP), but it still serves as an effective buffer.

Bone is an important buffer. Bone is basic—it is composed of compounds such as sodium bicarbonate and calcium carbonate—and thus, dissolution of bone releases base. This release can buffer an acid load, although at the expense of bone density, if it occurs over an extended period. In contrast, bone formation, by consuming base, helps buffer excess base.

Clinically, we measure the extracellular pH, but it is the intracellular pH that affects cell function. Measurement of the intracellular pH is unnecessary because changes in the intracellular pH parallel the changes in the extracellular pH. However, the change in the intracellular pH tends to be less than the change in the extracellular pH because of the greater buffering capacity in the intracellular space.

**NORMAL ACID–BASE BALANCE**

The lungs and kidneys maintain a normal acid–base balance. Carbon dioxide generated during normal metabolism is a weak acid. The lungs prevent an increase in the PCO₂ in the blood by excreting the CO₂ that the body produces. CO₂ production varies according to the body’s metabolic needs, increasing with physical activity. The rapid pulmonary response to changes in the CO₂ concentration occurs via central sensing of the PCO₂ and a subsequent increase or decrease in ventilation to maintain a normal PCO₂ (35-45 mm Hg). An increase in ventilation decreases the PCO₂, and a decrease in ventilation increases the PCO₂.

The kidneys excrete endogenous acid. An adult normally produces approximately 1-2 mEq/kg/24 hr of hydrogen ions. Children normally produce 2-3 mEq/kg/24 hr of hydrogen ions. The 3 principal sources of hydrogen ions are dietary protein metabolism, incomplete metabolism of carbohydrates and fat, and stool losses of bicarbonate. Because metabolism of protein generates hydrogen ions, endogenous acid production varies with protein intake. The complete oxidation of carbohydrates or fats to carbon dioxide and water does not generate hydrogen ions; the lungs remove the carbon dioxide. However, incomplete metabolism of carbohydrates or fats produces hydrogen ions. Incomplete glucose metabolism can produce lactic acid, and incomplete triglyceride metabolism can produce ketoc acids, such as β-hydroxybutyric acid and acetoacetic acid. There is always some baseline incomplete metabolism that contributes to endogenous acid production. This factor increases in pathologic conditions, such as lactic acidosis and diabetic ketoacidosis. Stool loss of bicarbonate is the third major source of endogenous acid production. The stomach secretes hydrogen ions,
but most of the remainder of the gastrointestinal tract secretes bicarbonate, and the net effect is a loss of bicarbonate from the body. To secrete bicarbonate, the cells of the intestine produce hydrogen ions that are released into the bloodstream. For each bicarbonate molecule lost in the stool, the body gains 1 hydrogen ion. This source of endogenous acid production is normally minimal but may increase dramatically in a patient with diarrhea.

The hydrogen ions formed from endogenous acid production are neutralized by bicarbonate, potentially causing the bicarbonate concentration to decrease. The kidneys regenerate this bicarbonate by secreting hydrogen ions. The lungs cannot regenerate bicarbonate, even though loss of carbon dioxide lowers the hydrogen ion concentration, as shown in the following reaction:

\[ \text{H}^+ + \text{HCO}_3^- \rightarrow \text{CO}_2 + \text{H}_2\text{O} \]

A decrease in CO₂ concentration causes the reaction to move to the right, which decreases the hydrogen ion concentration, but it also lowers the bicarbonate concentration. During a metabolic acidosis, hyperventilation can lower the CO₂ concentration, decrease the hydrogen ion concentration, and thus increase the pH. The underlying metabolic acidosis is still present. Similarly, the kidneys cannot correct an abnormally high CO₂ concentration, as shown in the following reaction:

\[ \text{H}^+ + \text{HCO}_3^- \rightarrow \text{CO}_2 + \text{H}_2\text{O} \]

An increase in the bicarbonate concentration also causes the reaction to move to the right, which increases the CO₂ concentration while simultaneously decreasing the hydrogen ion concentration. During a respiratory acidosis, increased renal generation of bicarbonate can decrease the hydrogen ion concentration and increase the pH, but cannot repair the respiratory acidosis. Both the lungs and the kidneys can affect the hydrogen ion concentration and hence the pH. However, only the lungs can regulate the CO₂ concentration, and only the kidneys can regulate the bicarbonate concentration.

**Renal Mechanisms**

The kidneys regulate the serum bicarbonate concentration by modifying acid excretion in the urine. This requires a 2-step process. First, the renal tubules resorb the bicarbonate that is filtered at the glomerulus. Second, there is tubular secretion of hydrogen ions. The urinary excretion of hydrogen ions generates bicarbonate that neutralizes endogenous acid production. The tubular actions necessary for renal acid excretion occur throughout the nephron (Fig. 55-6).

The resorption of filtered bicarbonate is a necessary first step in renal regulation of the acid–base balance. A normal adult has a GFR of approximately 180 L/24 hr. This fluid enters the Bowman space with a bicarbonate concentration that is essentially identical to the plasma concentration, normally 24 mEq/L. Multiplying 180 L by 24 mEq/L indicates that >4,000 mEq of bicarbonate enters the Bowman space each day. This bicarbonate, if not reclaimed along the nephron, would be lost in the urine and would cause a profound metabolic acidosis.

The proximal tubule reclaims approximately 85% of the filtered bicarbonate (Fig. 55-7). The final 15% is reclaimed beyond the proximal tubule, mostly in the ascending limb of the loop of Henle. Bicarbonate molecules are not transported from the tubular fluid into the cells of the proximal tubule. Rather, hydrogen ions are secreted into the tubular fluid, leading to conversion of filtered bicarbonate into CO₂ and water. The secretion of hydrogen ions by the cells of the proximal tubule is coupled to generation of intracellular bicarbonate, which is transported across the basolateral membrane of the proximal tubule cell and enters the capillaries. The bicarbonate produced in the cell replaces the bicarbonate filtered at the glomerulus.

Increased bicarbonate resorption by the cells of the proximal tubule—the result of increased hydrogen ion secretion—occurs in a variety of clinical situations. Volume depletion increases bicarbonate resorption. This is partially mediated by activation of the renin–angiotensin system; angiotensin II increases bicarbonate resorption. Increased bicarbonate resorption in the proximal tubule is one of the mechanisms that accounts for the metabolic alkalosis that may occur in some patients with volume depletion. Other stimulants that increase bicarbonate resorption include hypokalemia and an increased PCO₂. This partially explains the observations that hypokalemia causes a metabolic alkalosis and that a respiratory acidosis leads to a compensatory increase in serum bicarbonate concentration.

Stimuli that decrease bicarbonate resorption in the proximal tubule may cause a decrease in the serum bicarbonate concentration. A decrease in the PCO₂ (respiratory alkalosis) decreases proximal tubule bicarbonate resorption, partially mediating the decrease in serum bicarbonate concentration that compensates for a respiratory alkalosis.

![Figure 55-7 Resorption of filtered bicarbonate in the proximal tubule.](image-url)
PTH decreases proximal tubule bicarbonate resorption; hyperparathyroidism may cause a mild metabolic acidosis. A variety of medications and diseases cause a metabolic acidosis by impairing bicarbonate resorption in the proximal tubule. Examples are the medication acetazolamide, which directly inhibits carbonic anhydrase, and the many disorders that cause proximal RTA (see Chapter 329).

After reclaiming filtered bicarbonate, the kidneys perform the second step in renal acid-base handling, the excretion of the acid created by endogenous acid production. Excretion of acid occurs mostly in the collecting duct, with a small role for the distal tubule.

Along with secretion of hydrogen ions by the tubular cells lining the collecting duct, adequate excretion of endogenous acid requires the presence of urinary buffers. The hydrogen pumps in the collecting duct cannot lower the urine pH below 4.5. The hydrogen ion concentration at pH 4.5 is <0.04 mEq/L; it would require >25 L of water with a pH of 4.5 to excrete 1 mEq of hydrogen ions. A 10-kg child, with an endogenous acid production of 20 mEq of hydrogen ions each day, would need to have a daily urinary output of >500 L without the presence of urinary buffers. As in the blood, buffers in the urine attenuate the decrease in pH that occurs with the addition of hydrogen ions. The 2 principal urinary buffers are phosphate and ammonia.

Urinary phosphate is proportional to dietary intake. Whereas most of the phosphate filtered at the glomerulus is resorbed in the proximal tubule, the urinary phosphate concentration is usually much greater than the serum phosphate concentration. This arrangement allows phosphate to serve as an effective buffer via the following reaction:

\[ \text{H}^+ + \text{HPO}_4^{2-} \rightarrow \text{H}_2\text{PO}_4^- \]

The pK of this reaction is 6.8, making phosphate an effective buffer as the urinary pH decreases from 7.0 to 5.0 within the collecting duct. Although phosphate is an effective buffer, its buffering capacity is limited by its concentration; there is no mechanism for increasing urinary phosphate excretion in response to changes in acid–base status.

In contrast, ammonia production can be modified, allowing for regulation of acid excretion. The buffering capacity of ammonia is based on the reaction of ammonia with hydrogen ions to form ammonium:

\[ \text{NH}_3 + \text{H}^+ \rightarrow \text{NH}_4^+ \]

The cells of the proximal tubule are the source of the excreted ammonia, mostly through metabolism of glutamine via the following reactions:

\[ \text{Glutamine} \rightarrow \text{NH}_4^+ + \text{glutamate} \]
\[ \text{Glutamine}^- \rightarrow \text{NH}_4^+ + \alpha\text{-ketoglutarate} \]

The metabolism of glutamine generates 2 ammonium ions. In addition, the metabolism of α-ketoglutarate generates 2 bicarbonate molecules. The ammonium ions are secreted into the lumen of the proximal tubule, whereas the bicarbonate molecules exit the proximal tubule cells via the basolateral Na\textsuperscript{+}3HCO\textsubscript{3}\textsuperscript{−}/cotransporter (see Fig. 55-6). This arrangement would seem to accomplish the goal of excreting hydrogen ions (as NH\textsubscript{4}\textsuperscript{+}) and regenerating bicarbonate molecules. However, the ammonium ions secreted in the proximal tubule do not remain within the tubular lumen. Cells of the TAL of the loop of Henle resorb the ammonium ions. The result is that there is a high medullary interstitial concentration of ammonia, but the tubular fluid entering the collecting duct does not have significant amounts of ammonium ions. Moreover, the hydrogen ions that were secreted with ammonia, as ammonium ions, in the proximal tubule enter the bloodstream, canceling the effect of the bicarbonate generated in the proximal tubule. The excretion of ammonium ions, and hence of hydrogen ions, depends on the cells of the collecting duct.

The cells of the collecting duct secrete hydrogen ions and regenerate bicarbonate, which is returned to the bloodstream (Fig. 55-8). This bicarbonate neutralizes endogenous acid production. Phosphate and ammonia buffer the hydrogen ions secreted by the collecting duct. Ammonia is an effective buffer because of the high concentrations in the medullary interstitium and because the cells of the collecting duct are permeable to ammonia but not to ammonium. As ammonia diffuses into the lumen of the collecting duct, the low urine pH causes almost all of the ammonia to be converted into ammonium. This process maintains a low luminal ammonia concentration. Because the luminal pH is lower than the pH in the medullary interstitium, there is a higher concentration of ammonia within the medullary interstitium than in the tubular lumen, favoring movement of ammonia into the tubular lumen. Even though the concentration of ammonium in the tubular lumen is higher than in the interstitium, the cells of the collecting duct are impermeable to ammonium, preventing back-diffusion of ammonium out of the tubular lumen and permitting ammonia to be an effective buffer. The kidneys adjust hydrogen ion excretion according to physiologic needs. There is variation in endogenous acid production, largely a result of diet and pathophysiologic stresses, such as diarrheal losses of bicarbonate, which increase the need for acid excretion. Hydrogen excretion is increased by upregulation of hydrogen ion secretion in the collecting duct, causing the pH of the urine to decrease. This response is fairly prompt, occurring within hours of an acid load, but it is limited by the buffering capacity of the urine; the hydrogen pumps in the collecting duct cannot lower the pH to <4.5. A more significant increase in acid excretion requires upregulation of ammonia production by the proximal tubule so that more ammonia is available to serve as a buffer in the tubular lumen of the collecting duct. This response to a low serum pH reaches its maximum within 5-6 days; ammonia excretion can increase approximately 10-fold over the baseline value.

Acid excretion by the collecting duct increases in a number of different clinical situations. The extracellular pH is the most important regulator of renal acid excretion. A decrease in the extracellular pH from either a respiratory or a metabolic acidosis causes an increase in renal acid excretion. Aldosterone stimulates hydrogen ion excretion in the collecting duct, causing an increase in the serum bicarbonate concentration. This explains the metabolic alkalosis that occurs with primary hyperaldosteronism or secondary hyperaldosteronism caused by volume depletion. Hypokalemia increases acid secretion, by both stimulating ammonia production in the proximal tubule and increasing hydrogen ion secretion in the collecting duct. Hypokalemia therefore tends to produce a metabolic alkalosis. Hyperkalemia has the opposite effects, which may cause a metabolic acidosis.

In patients with an increased pH, the kidney has 2 principal mechanisms for correcting the problem. First, less bicarbonate is resorbed in the proximal tubule, leading to an increase in urinary bicarbonate...
losses. Second, in a limited number of specialized cells, the process for secretion of hydrogen ions by the collecting duct (see Fig. 55-8) can be reversed, leading to secretion of bicarbonate into the tubular lumen and secretion of hydrogen ions into the peritubular fluid, where they enter the bloodstream.

**CLINICAL ASSESSMENT OF ACID–BASE DISORDERS**

The following equation, a rearrangement of the Henderson–Hasselbalch equation, emphasizes the relationship among the PCO₂, the bicarbonate concentration, and the hydrogen ion concentration:

\[
[H^+] = 24 \times \frac{PCO_2}{[HCO_3^-]}
\]

An increase in the PCO₂ or a decrease in the bicarbonate concentration increases the hydrogen ion concentration; the pH decreases. A decrease in the PCO₂ or an increase in the bicarbonate concentration decreases the hydrogen ion concentration; the pH increases.

**Terminology**

Acidemia is a pH below normal (<7.35), and alkalemia is a pH above normal (>7.45). An acidosis is a pathologic process that causes an increase in the hydrogen ion concentration, and an alkalosis is a pathologic process that causes a decrease in the hydrogen ion concentration. Whereas acidemia is always accompanied by an acidosis, a patient can have an acidosis and a low, normal, or high pH. For example, a patient may have a mild metabolic acidosis but a simultaneous, severe respiratory alkalosis; the net result may be alkalemia. Acidemia and alkalemia indicate the pH abnormality; acidosis and alkalosis indicate the pathologic process that is taking place.

A simple acid–base disorder is a single primary disturbance. During a simple metabolic disorder, there is respiratory compensation. With a metabolic acidosis, the decrease in the pH increases the ventilatory drive, causing a decrease in the PCO₂. The decrease in the CO₂ concentration leads to an increase in the pH. This appropriate respiratory compensation is expected with a primary metabolic acidosis. Despite the decrease in the CO₂ concentration, appropriate respiratory compensation is not a respiratory alkalosis, even though it is sometimes erroneously called a compensatory respiratory alkalosis. A low PCO₂ can be either the result of a primary respiratory alkalosis or of an appropriate respiratory compensation for a metabolic acidosis. Appropriate respiratory compensation also occurs with a primary metabolic alkalosis, although in this case the CO₂ concentration increases to attenuate the increase in the pH. The respiratory compensation for a metabolic process happens quickly and is complete within 12-24 hr; it cannot overcompensate for or normalize the pH.

During a primary respiratory process, there is metabolic compensation, mediated by the kidneys. The kidneys respond to a respiratory acidosis by increasing hydrogen ion excretion, thereby increasing bicarbonate generation and raising the serum bicarbonate concentration. The kidneys increase bicarbonate excretion to compensate for a respiratory alkalosis; the serum bicarbonate concentration decreases. Unlike respiratory compensation, which occurs rapidly, it takes 3-4 days for the kidneys to complete appropriate metabolic compensation. There is, however, a small and rapid compensatory change in the bicarbonate concentration during a primary respiratory process. The expected appropriate metabolic compensation for a respiratory disorder depends on whether the process is acute or chronic.

A mixed acid–base disorder is present when there is more than 1 primary acid–base disturbance. An infant with bronchopulmonary dysplasia may have a respiratory acidosis from chronic lung disease and a metabolic alkalosis from the furosemide used to treat the chronic lung disease. More dramatically, a child with pneumonia and sepsis may have severe acidemia as a result of a combined metabolic acidosis caused by lactic acid and respiratory acidosis caused by ventilatory failure.

There are formulas for calculating the appropriate metabolic or respiratory compensation for the 6 primary simple acid–base disorders (Table 55-11). The appropriate compensation is expected in a simple disorder; it is not optional. If a patient does not have the appropriate compensation, then a mixed acid–base disorder is present. A patient has a primary metabolic acidosis with a serum bicarbonate concentration of 10 mEq/L. The expected respiratory compensation is a CO₂ concentration of 23 mm Hg ± 1 (1.5 × 10 + 8 ± 2 = 23 ± 2; Table 55-11). If the patient's CO₂ concentration is >25 mm Hg, a concurrent respiratory acidosis is present; the CO₂ concentration is higher than expected. A patient may have a respiratory acidosis despite a CO₂ level below the “normal” value of 35-45 mm Hg. In this example, a CO₂ concentration <21 mm Hg indicates a concurrent respiratory alkalosis; the CO₂ concentration is lower than expected.

**Diagnosis**

A systematic evaluation of an arterial blood gas sample, combined with the clinical history, can usually explain the patient's acid–base disturbance. Assessment of an arterial blood gas sample requires knowledge of normal values (Table 55-12). In most cases, this is accomplished via a 3-step process (Fig. 55-9):

- Determine whether acidemia or alkalemia is present.
- Determine whether acidemia or alkalemia is present.
- Determine whether a mixed disorder is present.

Most patients with an acid–base disturbance have an abnormal pH, although there are 2 exceptions. The first exception is in the patient with a mixed disorder, wherein the 2 processes have opposite effects on pH (a metabolic acidosis and a respiratory alkalosis) and cause changes in the hydrogen ion concentration that are comparable in magnitude, albeit opposite. The second exception is in the patient with a simple chronic respiratory alkalosis; in some instances, the appropriate metabolic compensation is enough to normalize the pH. In both of these situations, the presence of an acid–base disturbance is deduced because of the abnormal CO₂ and/or bicarbonate levels. Determining the acid–base disturbance in these situations requires proceeding to the third step of this process.

The second step requires inspection of the serum bicarbonate and CO₂ concentrations to determine a cause of the abnormal pH (see Fig. 55-9). In most cases, there is only 1 obvious explanation for the abnormal pH. In some mixed disorders, however, there may be 2 possibilities (a high PCO₂ and a low [HCO₃⁻] in a patient with acidemia). In such cases, the patient has 2 causes for abnormal pH (a metabolic acidosis and a respiratory acidosis, in this instance), and it is unnecessary to proceed to the third step.

The third step requires determining whether the patient's compensation is appropriate. It is assumed that the primary disorder
was diagnosed in the second step, and the expected compensation is calculated (see Table 55-11). If the compensation is appropriate, then a simple acid–base disorder is present. If the compensation is not appropriate, then a mixed disorder is present. The identity of the second disorder is determined by deciding whether the compensation is too little or too much compared with what was expected (see Fig. 55-9).

The history is always useful in evaluating and diagnosing patients with acid–base disturbances. It is especially helpful in a respiratory process. The expected metabolic compensation for a respiratory process changes according to whether the process is acute or chronic, which can be deduced only from the history. The metabolic compensation for an acute respiratory acidosis is less than that for a chronic respiratory acidosis. In a patient with a respiratory acidosis, a small increase in the bicarbonate concentration would be consistent with a simple acute respiratory acidosis or a mixed disorder (a chronic respiratory acidosis and a metabolic acidosis). Only the history can differentiate among the possibilities. Knowledge of the length of the respiratory process and the presence or absence of a risk factor for a metabolic acidosis (diarrhea) allows the correct conclusion to be reached.

**METABOLIC ACIDOSIS**

Metabolic acidosis occurs frequently in hospitalized children; diarrhea is the most common etiology. For a patient with an unknown medical problem, the presence of a metabolic acidosis is often helpful diagnostically, because it suggests a relatively narrow differential diagnosis.

Patients with a metabolic acidosis have a low serum bicarbonate concentration, although not every patient with a low serum bicarbonate concentration has a metabolic acidosis. The exception is the patient with a respiratory alkalosis, which causes a decrease in the serum bicarbonate concentration as part of appropriate renal compensation. In a patient with an isolated metabolic acidosis, there is a predictable decrease in the blood CO2 concentration, as follows:

\[
\text{PCO}_2 = 1.5 \times [\text{HCO}_3^-] + 8 \pm 2
\]

A mixed acid–base disturbance is present if the respiratory compensation is not appropriate. If the PCO2 is greater than predicted, then the patient has a concurrent respiratory acidosis. A lower PCO2 than predicted indicates a concurrent respiratory alkalosis or, less commonly, an isolated respiratory alkalosis. Because the appropriate respiratory compensation for a metabolic acidosis never normalizes the patient's pH, the presence of a normal pH and a low bicarbonate concentration occurs only if some degree of respiratory alkalosis is present. In this situation, distinguishing an isolated chronic respiratory alkalosis from a mixed metabolic acidosis and acute respiratory alkalosis may be possible only clinically. In contrast, the combination of a low serum pH and a low bicarbonate concentration occurs only if a metabolic acidosis is present.

**Etiology and Pathophysiology**

There are many causes of a metabolic acidosis (Table 55-13), which occur via 3 basic mechanisms:

- **Loss of bicarbonate from the body**
- **Impaired ability to excrete acid by the kidney**
- **Addition of acid to the body (exogenous or endogenous)**

**Diarrhea**, the most common cause of metabolic acidosis in children, causes a loss of bicarbonate from the body. The amount of bicarbonate lost in the stool depends on the volume of diarrhea and the bicarbonate concentration of the stool, which tends to increase with more severe diarrhea. The kidneys attempt to balance the losses by increasing acid secretion, but metabolic acidosis occurs when this compensation is inadequate. Diarrhea often causes volume depletion as a result of losses of sodium and water, potentially exacerbating the acidosis by causing shock and a lactic acidosis. In addition, diarrhoeal losses of potassium lead to hypokalemia. Moreover, the volume depletion causes increased production of aldosterone. This increase stimulates renal retention of sodium, helping to maintain intravascular volume, but also leads to increased urinary losses of potassium, exacerbating the hypokalemia.

There are 3 forms of RTA: distal (type I), proximal (type II), and hyperkalemic (type IV) (see Chapter 529). In distal RTA, children may have accompanying hypokalemia, hypercalcemia, nephrolithiasis, and nephrocalcinosis. Failure to thrive because of chronic metabolic acidosis is the most common presenting complaint. Patients with distal RTA cannot acidify their urine and, thus, have a urine pH >5.5 despite a metabolic acidosis.

Proximal RTA is rarely present in isolation. In most patients, proximal RTA is part of Fanconi syndrome, a generalized dysfunction of the proximal tubule. The dysfunction leads to glycosuria, aminoaciduria, and excessive urinary losses of phosphate and uric acid. The presence of a low serum uric acid level, glycosuria, and aminoaciduria is helpful diagnostically. Chronic hypophosphatemia leads to rickets in children (see Chapter 51). Rickets and/or failure to thrive may be the presenting complaint. The ability to acidify the urine is intact in proximal RTA; thus, untreated patients have a urine pH <5.5. However, bicarbonate therapy increases bicarbonate losses in the urine, and the urine pH increases.

In hyperkalemic RTA, renal excretion of acid and potassium is impaired. Hyperkalemic RTA is the result of either an absence of

---

**Figure 55-9** Three-step process for interpreting acid–base disturbances. In step 1, determine whether the pH is low (acidemia) or high (alkalemia). In step 2, establish an explanation for the acidemia or alkalemia. In step 3, calculate the expected compensation (see Table 55-11) and determine whether a mixed disturbance is present. Met. Acid., metabolic acidosis; Met. Alk., metabolic alkalosis; Resp. Acid., respiratory acidosis; Resp. Alk., respiratory alkalosis.

*Along with these genetic disorders, distal RTA may be secondary to renal disease or medications.

† Most cases of proximal RTA are not caused by this primary genetic disorder.

* Hypokalemic RTA can be secondary to a genetic disorder (some of the more common are listed) or other etiologies.

aldosterone or an inability of the kidney to respond to aldosterone. In severe aldosterone deficiency, as occurs with congenital adrenal hyperplasia because of 21α-hydroxylase deficiency, the hyperkalemia and metabolic acidosis are accompanied by hyponatremia and volume depletion from renal salt wasting. Incomplete aldosterone deficiency causes less-severe electrolyte disturbances; children may have isolated hyperkalemic RTA, hyperkalemia without acidosis, or isolated hyponatremia. Patients may have aldosterone deficiency caused by decreased renin production by the kidney; renin normally stimulates aldosterone synthesis. Children with hyporeninemic hypoaldosteronism usually have either isolated hyperkalemia or hyperkalemic RTA. The manifestations of aldosterone resistance depend on the severity of the resistance. In the autosomal recessive form of pseudohypoaldosteronism type I, which is the result of an absence of the sodium channel that normally responds to aldosterone, there is often severe salt wasting and hyponatremia. In contrast, the aldosterone resistance in kidney transplant recipients usually produces either isolated hyperkalemia or hyperkalemic RTA; hyponatremia is unusual. Similarly, the medications that cause hyperkalemic RTA do not cause hyponatremia. Pseudohypoaldosteronism type II, an autosomal recessive disorder also known as Gordon syndrome, is a unique cause of hyperkalemic RTA because the genetic defect causes volume expansion and hypertension.

Children with abnormal urinary tracts, usually secondary to congenital malformations, may require diversion of urine through intestinal segments. Ureterosigmoidostomy, anastomosis of a ureter to the sigmoid colon, almost always produces a metabolic acidosis and hypokalemia. Consequently, ileal conduits are now the more commonly used procedure, although there is still a risk of a metabolic acidosis.

The appropriate metabolic compensation for a chronic respiratory alkalosis is a decrease in renal acid excretion. The resultant decrease in the serum bicarbonate concentration lessens the alkalemia caused by the respiratory alkalosis. If the respiratory alkalosis resolves quickly, the patient continues to have a decreased serum bicarbonate concentration, causing acidemia as the result of a metabolic acidosis. This resolves over 1-2 days via increased acid excretion by the kidneys.

Lactic acidosis most commonly occurs when inadequate oxygen delivery to the tissues leads to anaerobic metabolism and excess production of lactic acid. Lactic acidosis may be secondary to shock, severe anemia, or hypoxemia. When the underlying cause of the lactic acidosis is alleviated, the liver is able to metabolize the accumulated lactate into bicarbonate, correcting the metabolic acidosis. There is normally some tissue production of lactate that is metabolized by the liver. In children with severe liver dysfunction, impairment of lactate metabolism may produce a lactic acidosis. Rarely, a metabolically active malignancy grows so fast that its blood supply becomes inadequate, with resultant anaerobic metabolism and lactic acidosis. Patients who have short bowel syndrome resulting from small bowel resection can have bacterial overgrowth. In these patients, excessive bacterial metabolism of glucose into d-lactic acid can cause a lactic acidosis. Lactic acidosis occurs in a variety of inborn errors of metabolism, especially those affecting mitochondrial oxidation (see Chapter 87.4).

Finally, medications can cause lactic acidosis. Nucleoside reverse transcriptase inhibitors that are used to treat HIV infection inhibit mitochondrial replication; lactic acidosis is a rare complication, although elevated serum lactate concentrations without acidosis are quite common. Metformin, commonly used for treating type 2 diabetes mellitus, is most likely to cause a lactic acidosis in patients with renal insufficiency. High dosages and prolonged use of propofol can cause lactic acidosis. Propylene glycol is a diluent in a variety of oral and intravenous medications; excessive intake causes a lactic acidosis, principally from accumulation of d-lactic acid.

In insulin-dependent diabetes mellitus, inadequate insulin leads to hyperglycemia and diabetic ketoacidosis (see Chapter 589). Production of acetoacetic acid and β-hydroxybutyric acid causes the metabolic acidosis. Administration of insulin corrects the underlying metabolic problem and permits conversion of acetoacetate and β-hydroxybutyrate into bicarbonate, which helps correct the metabolic acidosis. However, in some patients, urinary losses of acetoacetic acid and β-hydroxybutyrate may be substantial, preventing rapid regeneration of bicarbonate. In these patients, full correction of the metabolic acidosis requires renal regeneration of bicarbonate, a slower process. The hyperglycemia causes an osmotic diuresis, usually producing volume depletion, along with substantial losses of potassium, sodium, and phosphate.

In starvation ketoacidosis, the lack of glucose leads to keto acid production, which, in turn, can produce a metabolic acidosis, although it is usually mild as a result of increased acid secretion by the kidney. In alcoholic ketoacidosis, which is much less common in children than in adults, the acidosis usually follows a combination of an alcoholic binge with vomiting and poor intake of food. The acidosis is potentially more severe than with isolated starvation, and the blood glucose level may be low, normal, or high. Hypoglycemia and acidosis also suggest an inborn error of metabolism.

Renal failure causes a metabolic acidosis because of the need for the kidneys to excrete the acid produced by normal metabolism. With mild or moderate renal insufficiency, the remaining nephrons are usually able to compensate by increasing acid excretion. When the GFR is <20-30% of normal, the compensation is inadequate and a metabolic acidosis develops. In some children, especially those with chronic renal failure because of tubular damage, the acidosis develops at a higher GFR because of a concurrent defect in acid secretion by the distal tubule (distal RTA).

A variety of toxic ingestions (see Chapter 63) can cause a metabolic acidosis. Salicylate intoxication is now much less common because aspirin is no longer recommended for fever control in children. Acute
salicylate intoxication occurs after a large overdose. Chronic salicylate intoxication is possible with gradual buildup of the drug. Especially in adults, respiratory alkalosis may be the dominant acid–base disturbance. In children, the metabolic acidosis is usually the more significant finding. Other symptoms of salicylate intoxication are fever, seizures, lethargy, and coma. Hyperventilation may be particularly marked. Tinnitus, vertigo, and hearing impairment are more likely with chronic salicylate intoxication.

**Ethylene glycol**, a component of antifreeze, is converted in the liver to glyoxylic and oxalic acids, causing a severe metabolic acidosis. Excessive oxalate excretion causes calcium oxalate crystals to appear in the urine, and calcium oxalate precipitation in the kidney tubules can cause renal failure. The toxicity of methanol ingestion also depends on liver metabolism; formic acid is the toxic end product that causes the metabolic acidosis and other sequelae, which include damage to the optic nerve and CNS. Symptoms may include nausea, emesis, visual impairment, and altered mental status. Toluene inhalation and paralytic dehydration ingestion are other potential causes of a metabolic acidosis.

Many inborn errors of metabolism cause a metabolic acidosis (see Chapters 84–87). The metabolic acidosis may be the result of excessive production of keto acids, lactic acid, and/or other organic anions. Some patients have accompanying hypoglycemia or hyperammonemia. In most patients, the acidosis occurs episodically, only during acute decompensations, which may be precipitated by ingestion of specific dietary substrates, the stress of a mild illness, or poor compliance with dietary or medical therapy. In a few inborn errors of metabolism, patients have a chronic metabolic acidosis.

**Clinical Manifestations**
The underlying disorder usually produces most of the signs and symptoms in children with a mild or moderate metabolic acidosis. The clinical manifestations of the acidosis are related to the degree of acidemia; patients with appropriate respiratory compensation and less severe acidemia have fewer manifestations than those with a concomitant respiratory acidosis. At a serum pH < 7.2, there may be impaired cardiac contractility and an increased risk of arrhythmias, especially if underlying heart disease or other predisposing electrolyte disorders are present. With acidemia, there may be a decrease in the cardiovascular response to catecholamines, potentially exacerbating hypotension in children with volume depletion or shock. Acidemia causes vasoconstriction of the pulmonary vasculature, which is especially problematic in newborn infants with persistent pulmonary hypertension (see Chapter 101.7).

The normal respiratory response to metabolic acidosis—compensatory hyperventilation—may be subtle with mild metabolic acidosis, but it causes discernible increased respiratory effort with worsening acidemia. The acute metabolic effects of acidemia include insulin resistance, increased protein degradation, and reduced ATP synthesis. Chronic metabolic acidosis causes failure to thrive in children. Acidemia causes potassium to move from the intracellular space to the extracellular space, thereby increasing the serum potassium concentration. Severe acidemia impairs brain metabolism, eventually resulting in lethargy and coma.

**Diagnosis**
The etiology of a metabolic acidosis is often apparent from the history and physical examination. Acutely, diarrhea and shock are common causes of a metabolic acidosis. Shock, which causes a lactic acidosis, is usually apparent on physical examination and can be secondary to dehydration, acute blood loss, sepsis, or heart disease. Failure to thrive suggests a chronic metabolic acidosis, as happens with renal insufficiency or RTA. New onset of polyuria occurs in children with undiagnosed diabetes mellitus and diabetic ketoacidosis. Metabolic acidosis with seizures and/or a depressed sensorium, especially in an infant, warrants consideration of an inborn error of metabolism. Meningitis and sepsis with lactic acidosis are more common explanations for metabolic acidosis with neurologic signs and symptoms. Identification of a toxic ingestion such as of ethylene glycol or methanol is especially important because of the potentially excellent response to specific therapy. A variety of medications can cause a metabolic acidosis; they may be prescribed or accidentally ingested. Hepatomegaly and metabolic acidosis may occur in children with sepsis, congenital or acquired heart disease, hepatic failure, or inborn errors of metabolism.

Basic laboratory tests in a child with a metabolic acidosis should include measurements of BUN, serum creatinine, serum glucose, urinalysis, and serum electrolytes. Elevated BUN and creatinine values are present in renal insufficiency, whereas an elevated BUN:creatinine ratio (>20:1) supports a diagnosis of prerenal azotemia and the possibility of poor perfusion with lactic acids. Metabolic acidosis, hyperglycemia, glycosuria, and ketonuria support a diagnosis of diabetic ketoacidosis. Starvation causes ketosis, but the metabolic acidosis, if present, is usually mild (HCO$_3^-$ > 18). In most children with ketosis from poor intake and metabolic acidosis there is a concomitant disorder, such as gastroenteritis with diarrhea, that explains the metabolic acidosis. Alternatively, metabolic acidosis with or without ketosis occurs in inborn errors of metabolism; patients with these disorders may have hyperglycemia, normoglycemia, or hypoglycemia. Adrenal insufficiency may cause metabolic acidosis and hypoglycemia. Metabolic acidosis with hypoglycemia also occurs with liver failure. Metabolic acidosis, normoglycemia, and glycosuria occur in children when type II RTA is part of Fanconi syndrome; the defect in resorption of glucose by the proximal tubule of the kidney causes the glycosuria.

The serum potassium level is often abnormal in children with a metabolic acidosis. Even though a metabolic acidosis causes potassium to move from the intracellular space to the extracellular space, many patients with a metabolic acidosis have a low serum potassium level owing to excessive body losses of potassium. In diabetes, there are high stool losses of potassium and often secondary renal losses of potassium, whereas in type I or type II RTA, there are increased urinary losses of potassium. In diabetic ketoacidosis, urinary losses of potassium are high, but the shift of potassium out of cells because of a lack of insulin and metabolic acidosis is especially significant. Consequently, the initial serum potassium level can be low, normal, or high, even though total body potassium is almost always decreased. The serum potassium level is usually increased in patients with acidosis due to renal insufficiency; urinary potassium excretion is impaired. The combination of metabolic acidosis, hyperkalemia, and hyponatremia occurs in patients with severe aldosterone deficiency (adenogenital syndrome) or aldosterone resistance. Patients with less severe, type IV RTA often have only hyperkalemia and metabolic acidosis. Very ill children with metabolic acidosis may have an elevated serum potassium value as a result of a combination of renal insufficiency, tissue breakdown, and a shift of potassium from the intracellular space to the extracellular space secondary to the metabolic acidosis.

The plasma anion gap is useful for evaluating patients with a metabolic acidosis. It divides patients into 2 diagnostic groups, those with normal anion gap and those with increased anion gap. The following formula determines the anion gap:

$$\text{Anion gap} = [\text{Na}^+] - [\text{Cl}^-] - [\text{HCO}_3^-]$$

A normal anion gap is 4–11, although there is variation among laboratories. The number of serum anions must equal the number of serum cations to maintain electrical neutrality (Fig. 55-10). The anion gap is the difference between the measured cation (sodium) and the measured anions (chloride + bicarbonate). The anion gap is also the difference between the unmeasured cations (potassium, magnesium, calcium) and the unmeasured anions (albumin, phosphate, urate, sulfate). An increased anion gap occurs when there is an increase in unmeasured anions. With a lactic acidosis, there is endogenous production of lactic acid, which is composed of positively charged hydrogen ions and negatively charged lactate anions. The hydrogen ions are largely buffered by serum bicarbonate, resulting in a decrease in the bicarbonate concentration. The hydrogen ions that are not buffered by bicarbonate cause the serum pH to decrease. The lactate anions remain, causing the increase in the anion gap.

An increase in unmeasured anions, along with hydrogen ion generation, is present in all causes of an increased gap metabolic acidosis (see Table 55-13). In diabetic ketoacidosis, the keto acids β-hydroxybutyrate
and chloride the of concentrations serum chloride concentration. UC, unmeasured cations. Acidosis. In a nongap metabolic acidosis, there is an increase in the bicarbonate concentration. There is thus a mix of an increased gap and a normal gap metabolic acidosis.

The normal gap metabolic acidosis is especially prominent in children with renal failure as a result of tubular damage, as occurs with renal dysplasia or obstructive uropathy, because these patients have a concurrent RTA. The unmeasured anions in toxic ingestions vary: formate in methanol intoxication, glycolate in ethylene glycol intoxication, and lactate and keto acids in salicylate intoxication. In inborn errors of metabolism, the unmeasured anions depend on the specific etiology which includes hypokalemia and hypophosphatemia. Bicarbonate therapy increases the generation of CO₂, which can accumulate in patients with respiratory failure. Because CO₂ readily diffuses into cells, the administration of bicarbonate can lower the intracellular pH, potentially worsening cell function. Base therapy is usually reserved for children with severe acute lactic acidosis and severe diabetic ketoacidosis.

**Oral base therapy** is given to children with chronic metabolic acidosis. Sodium bicarbonate tablets are available for older children. Younger children generally take citrate solutions; the liver generates bicarbonate from citrate. Citrate solutions are available as sodium citrate, potassium citrate, and a 1:1 mix of sodium citrate and potassium citrate. The patient's potassium needs dictate the choice. Children with type I or type II RTA may have hypokalemia and may benefit from potassium supplements, whereas most children with chronic renal failure cannot tolerate additional potassium.

Oral or intravenous base can be used in acute metabolic acidosis; intravenous therapy is generally used when a rapid response is necessary. Sodium bicarbonate may be given as a bolus, usually at a dose of 1 mEq/kg, in an emergency situation. Another approach is to add sodium bicarbonate or sodium acetate to the patient's intravenous fluids, remembering to remove an equal amount of sodium chloride from the solution to avoid giving an excessive sodium load. Careful monitoring is mandatory so that the dose of base can be titrated appropriately. Tris-hydroxymethyl aminomethane (THAM) is an option in patients with a metabolic acidosis and a respiratory acidosis, because it neutralizes acids without releasing CO₂. THAM also diffuses into cells and therefore provides intracellular buffering.

Hemodialysis is another option for correcting a metabolic acidosis, and it is an appropriate choice in patients with renal insufficiency, especially if significant uremia or hyperkalemia is also present. Hemodialysis is advantageous for correcting the metabolic acidosis caused by methanol or ethylene glycol intoxication, because hemodialysis removes the offending toxin. In addition, these patients often have a severe metabolic acidosis that does not respond easily to intravenous bicarbonate therapy. Peritoneal dialysis is another option for correcting the metabolic acidosis due to renal insufficiency, although, because it relies on lactate as the source of base, it may not correct the metabolic acidosis in patients with concomitant renal failure and lactic acidosis.

**Chapter 55 ♦ Electrolyte and Acid-Base Disorders**

**Figure 55-10** The anion gap, which is the difference between the sodium concentration and the combined concentrations of chloride and bicarbonate (vertical lines). In both a gap and a nongap metabolic acidosis, there is a decrease in the bicarbonate concentration. There is an increase in unmeasured anions (UA) in patients with a gap metabolic acidosis. In a nongap metabolic acidosis, there is an increase in the serum chloride concentration. UC, unmeasured cations.

**Table 55-7** The diagnostic utility of the anion gap. The anion gap is more precise than using the chloride concentration, making the chloride concentration a less reliable predictor of unmeasured anions than the more direct measure, calculation of the anion gap. Conversely, a decrease in unmeasured cations is a very unusual cause of an increased anion gap.

- **Normal anion gap** metabolic acidosis occurs when there is a decrease in the bicarbonate concentration without an increase in the unmeasured anions. With diarrhea, there is a loss of bicarbonate in the stool, causing a decrease in the serum pH and bicarbonate concentration; the serum chloride concentration increases to maintain electrical neutrality (see Fig. 55-10). Hyperchloremic metabolic acidosis is an alternative term for a normal anion gap metabolic acidosis. Calculation of the anion gap is more precise than using the chloride concentration to differentiate between a normal and an increased gap metabolic acidosis, in that the anion gap directly determines the presence of unmeasured anions. Electrical neutrality dictates that the chloride concentration increases or decreases according to the serum sodium concentration, making the chloride concentration a less reliable predictor of unmeasured anions than the more direct measure, calculation of the anion gap.

- **Approximately 11 mEq** of the anion gap is normally secondary to albumin. A 1 g/dL decrease in the albumin concentration decreases the anion gap by roughly 2.5 mEq/L. Similarly, an increase in unmeasured cations, such as calcium, potassium, and magnesium, decreases the anion gap. Conversely, a decrease in unmeasured cations is a very unusual cause of an increased anion gap. Because of these variables, the broad range of a normal anion gap, and other variables, the presence of a normal or an increased anion gap is not always reliable in differentiating among the causes of a metabolic acidosis, especially when the metabolic acidosis is mild. In some patients there is more than 1 explanation for the metabolic acidosis, such as the child with diarrhea and lactic acidosis as a result of poor perfusion. The anion gap should not be interpreted in dogmatic isolation; consideration of other laboratory abnormalities and the clinical history improves its diagnostic utility.

**Treatment**

The most effective therapeutic approach for patients with a metabolic acidosis is repair of the underlying disorder, if possible. The administration of insulin in diabetic ketoacidosis and the restoration of adequate perfusion with intravenous fluids in lactic acidosis because of hypovolemia or shock eventually result in normalization of the acid–base balance. In other diseases, the use of bicarbonate therapy is indicated because the underlying disorder is irreparable. Children with metabolic acidosis caused by RTA or chronic renal failure require long-term base therapy. Patients with acute renal failure and metabolic acidosis need base therapy until their kidneys’ ability to excrete hydrogen normalizes. In other disorders, the cause of the metabolic acidosis eventually resolves, but base therapy is necessary during the acute illness. In salicylate poisoning, alkali administration increases renal clearance of salicylate and decreases the amount of salicylate in brain cells. Short-term base therapy is often necessary in other poisonings (ethylene glycol, methanol) and inborn errors of metabolism (pyruvate carboxylase deficiency, propionic acidemia). Some inborn errors of metabolism require long-term base therapy.

The use of base therapy in diabetic ketoacidosis and lactic acidosis is controversial; there is little evidence that it improves patient outcome, and it has a variety of potential side effects. The risks of giving sodium bicarbonate include the possibility of causing hypernatremia or volume overload. Furthermore, the patient may have overcorrection of the metabolic acidosis once the underlying disorder resolves, because metabolism of lactate or keto acids generates bicarbonate. The rapid change from acidemia to alkalemia can cause a variety of problems, including hypokalemia and hypophosphatemia. Bicarbonate therapy increases the generation of CO₂, which can accumulate in patients with respiratory failure. Because CO₂ readily diffuses into cells, the administration of bicarbonate can lower the intracellular pH, potentially worsening cell function. Base therapy is usually reserved for children with severe acute lactic acidosis and severe diabetic ketoacidosis.
Many causes of metabolic acidosis require specific therapy. Administration of a glucocorticoid and a mineralocorticoid is necessary in patients with adrenal insufficiency. Patients with diabetic ketoacidosis require insulin therapy, whereas patients with lactic acidosis respond to measures that alleviate tissue hypoxia. Along with correction of acidosis, patients with methanol or ethylene glycol ingestion should receive an agent that prevents the breakdown of the toxic substance to its toxic metabolites. Fomepizole has supplanted ethanol as the treatment of choice. These agents work by inhibiting alcohol dehydrogenase, the enzyme that performs the first step in the metabolism of ethylene glycol or methanol. There are a variety of disease-specific therapies for patients with a metabolic acidosis resulting from an inborn error of metabolism.

**METABOLIC ALKALOSIS**

Metabolic alkalosis in children is most commonly secondary to emesis or diuretic use. The serum bicarbonate concentration is increased with a metabolic alkalosis, although a respiratory acidosis also leads to a compensatory elevation of the serum bicarbonate concentration. With a simple metabolic alkalosis, however, the pH is elevated; alkalemia is present. Patients with a respiratory acidosis are acidemic. A metabolic alkalosis, by decreasing ventilation, causes appropriate respiratory compensation. PCO2 decreases by 7 mm Hg for each 10 mEq/L increase in the serum bicarbonate concentration. Appropriate respiratory compensation never exceeds a PCO2 of 55-60 mm Hg. The patient has a concurrent respiratory alkalosis if the PCO2 is lower than the expected compensation. A greater-than-expected PCO2 occurs with a concurrent respiratory acidosis.

**Etiology and Pathophysiology**

The kidneys normally respond promptly to a metabolic alkalosis by increasing base excretion. Two processes are therefore usually present to produce a metabolic alkalosis. The first process is the generation of the metabolic alkalosis, which requires the addition of base to the body. The second process is the maintenance of the metabolic alkalosis, which requires impairment in the kidney’s ability to excrete base.

The etiologies of a metabolic alkalosis are divided into 2 categories on the basis of urinary chloride level (Table 55-14). The alkalosis in patients with a low urinary chloride level is maintained by volume depletion; thus, volume repletion is necessary for correction of the alkalosis. The volume depletion in these patients is caused by losses of sodium and potassium, but the loss of chloride is usually greater than the losses of sodium and potassium combined. Because chloride losses are the dominant cause of the volume depletion, these patients require chloride to correct the volume depletion and metabolic alkalosis; they are said to have chloride-responsive metabolic alkalosis. In contrast, the alkalosis in a patient with an elevated urinary chloride concentration does not respond to volume repletion and is termed chloride-resistant metabolic alkalosis.

Emesis or nasogastric suction results in loss of gastric fluid, which has a high content of HCl. Generation of hydrogen ions by the gastric mucosa causes simultaneous release of bicarbonate into the bloodstream. Normally, the hydrogen ions in gastric fluid are reclaimed in the small intestine (by neutralizing secreted bicarbonate). Thus, there is no net loss of acid. With loss of gastric fluid, this does not occur, and a metabolic alkalosis develops. This period is the generation phase of the metabolic alkalosis.

The maintenance phase of the metabolic alkalosis from gastric losses is due to the volume depletion (“chloride depletion” from gastric loss of HCl). Volume depletion interferes with urinary loss of bicarbonate, the normal renal response to a metabolic alkalosis. During volume depletion, several mechanisms prevent renal bicarbonate loss. First, there is a reduction in the GFR, so less bicarbonate is filtered. Second, volume depletion increases resorption of sodium and bicarbonate in the proximal tubule, limiting the amount of bicarbonate that can be excreted in the urine. This effect is mediated by angiotensin II and by adrenergic stimulation of the kidney, which are both increased in response to volume depletion. Third, the increase in aldosterone during volume depletion increases bicarbonate resorption and hydrogen ion secretion in the collecting duct.

In addition to volume depletion, gastric losses are usually associated with hypokalemia as a result of both gastric loss of potassium and, most importantly, increased urinary potassium losses. The increased urinary losses of potassium are mediated by aldosterone, through volume depletion, and by the increase in intracellular potassium secondary to the metabolic alkalosis, which causes potassium to move into the cells of the kidney, causing increased potassium excretion. Hypokalemia contributes to the maintenance of the metabolic alkalosis by decreasing bicarbonate loss. Hypokalemia increases hydrogen ion secretion in the distal nephron and stimulates ammonia production in the proximal tubule. Ammonia production enhances renal excretion of hydrogen ions.

A metabolic alkalosis can develop in patients receiving loop or thiazide diuretics. Diuretic use leads to volume depletion, which increases angiotensin II, aldosterone, and adrenergic stimulation of the kidney. Diuretics increase the delivery of sodium to the distal nephron, further enhancing acid excretion. Moreover, these diuretics cause hypokalemia, which increases acid excretion by the kidney. The increase in renal acid excretion generates the metabolic alkalosis, and the decrease in bicarbonate loss maintains it. In addition, patients who are receiving diuretics have a “contraction alkalosis.” Diuretic use causes fluid loss without bicarbonate; thus, the remaining body bicarbonate is contained in a smaller total body fluid compartment. The bicarbonate concentration increases, helping to generate the metabolic alkalosis.

Diuretics are often used in patients with edema, such as those with nephrotic syndrome, heart failure, or liver failure. In many of these patients, metabolic alkalosis resulting from diuretic use develops despite the continued presence of edema. This is because the effective intravascular volume is low, and it is the effective intravascular volume that stimulates the compensatory mechanisms that cause and maintain a metabolic alkalosis. Many of these patients have a decreased effective intravascular volume before they begin diuretic therapy, increasing the likelihood of diuretic-induced metabolic alkalosis.

Diuretic use increases chloride excretion in the urine. Consequently, while a patient is receiving diuretics, the urine chloride level is typically

High (>20 mEq/L). After the diuretic effect has worn off, the urinary chloride level is low (<15 mEq/L) owing to appropriate renal chloride retention in response to volume depletion. Thus, categorization of diuretics on the basis of urinary chloride level depends on the timing of the measurement. However, the metabolic alkalosis from diuretics is clearly chloride responsive; it is corrected after adequate volume repletion. This is the rationale for including this process among the chloride-responsive causes of a metabolic alkalosis.

Most patients with diarrhea have a metabolic acidosis as a result of stool losses of bicarbonate. In chloride-losing diarrhea, an autosomal recessive disorder, there is a defect in the normal intestinal exchange of bicarbonate for chloride, causing excessive stool losses of chloride (see Chapter 338). In addition, stool losses of hydrogen ions and potassium cause metabolic alkalosis and hypokalemia, both of which are exacerbated by increased renal hydrogen and potassium losses from volume depletion. Treatment is with oral supplements of potassium and sodium chloride. Use of a gastric proton pump inhibitor, by decreasing gastric HCl production, reduces both the volume of diarrhea and the need for electrolyte supplementation.

An infant formula with extremely low chloride content has led to chloride deficiency and volume depletion. The infants fed this formula, which is no longer available, had a metabolic alkalosis and hypokalemia. Cystic fibrosis can rarely cause metabolic alkalosis, hypokalemia, and hyponatremia because of excessive losses of sodium chloride in sweat (see Chapter 403). The volume depletion causes the metabolic alkalosis and hypokalemia through increased urinary losses, whereas the hyponatremia, a less-common finding, is secondary to sodium loss combined with renal water conservation in an effort to protect the intravascular volume (“appropriate” ADH production).

A posthypercapnic metabolic alkalosis occurs after the correction of a chronic respiratory acidosis. This is typically seen in patients with chronic lung disease who are started on mechanical ventilation. During chronic respiratory acidosis, appropriate renal compensation leads to an increase in the serum bicarbonate concentration. This elevated bicarbonate concentration, because it is still present after acute correction of the respiratory acidosis, causes a metabolic alkalosis. The metabolic alkalosis persists because the patient with a chronic respiratory acidosis is intravascularly depleted because of the chloride loss that occurred during the initial metabolic compensation for the primary respiratory acidosis. In addition, many children with a chronic respiratory acidosis receive diuretics, which further decrease the intravascular volume. The metabolic alkalosis responds to correction of the intravascular volume deficit.

The chloride-resistant causes of metabolic alkalosis can be subdivided according to blood pressure status. Patients with hypertension either have increased aldosterone levels or act as if they do. Aldosterone levels are elevated in children with adenal adenomas or hyperplasia. Aldosterone causes renal retention of sodium, with resultant hypertension. Metabolic alkalosis and hypokalemia result from aldosterone-mediated renal excretion of hydrogen ions and potassium. The urinary chloride level is not low because these patients are volume-overloaded, not volume-depleted. The volume expansion and hypertension allow normal excretion of sodium and chloride despite the presence of aldosterone. This is known as the mineralocorticoid escape phenomenon.

In glucocorticoid-remediable aldosteronism, an autosomal dominant disorder, there is excess production of aldosterone owing to the presence of an aldosterone synthase gene that is regulated by adrenocorticotropic hormone (ACTH) (see Chapter 576.8). Glucocorticoids effectively treat this disorder by inhibiting ACTH production by the pituitary, downregulating the inappropriate aldosterone production. Renovascular disease and renin-secreting tumors both cause excessive renin, leading to an increase in aldosterone, although hypokalemia and metabolic alkalosis are less-common findings than hypertension. In 2 forms of congenital adrenal hyperplasia, 11β-hydroxylase deficiency and 17α-hydroxylase deficiency, there is excessive production of the mineralocorticoid 11-deoxycorticosterone (see Chapters 576.2 and 576.4). Hypertension, hypokalemia, and metabolic alkalosis are more likely in 17α-hydroxylase deficiency than in 11β-hydroxylase deficiency. These disorders respond to glucocorticoids because the excess production of 11-deoxycorticosterone is under the control of ACTH.

Cushing syndrome frequently causes hypertension. Cortisol has some mineralocorticoid activity, and high levels can produce hypokalemia and metabolic alkalosis in patients with Cushing syndrome. Cortisol can bind to the mineralocorticoid receptors in the kidney and function as a mineralocorticoid. This binding normally does not occur because 11β-hydroxysteroid dehydrogenase in the kidney converts cortisol to cortisone, which does not bind to the mineralocorticoid receptor. In 11β-hydroxysteroid dehydrogenase deficiency, also called apparent mineralocorticoid excess, cortisol is not converted in the kidney to cortisone. Cortisol is therefore available to bind to the mineralocorticoid receptor in the kidney and act as a mineralocorticoid. Patients with this deficiency, despite low levels of aldosterone, are hypertensive and hypokalemic, and they have a metabolic alkalosis. The same phenomenon can occur with excessive intake of natural licorice, a component of which, glycyrrhizic acid, inhibits 11β-hydroxysteroid dehydrogenase. The autosomal dominant disorder Liddle syndrome is secondary to an activating mutation of the sodium channel in the distal nephron (see Chapter 531.3). Upregulation of this sodium channel is one of the principal actions of aldosterone. Because this sodium channel is continuously open, children with Liddle syndrome have the features of hyperaldosteronism, including hypertension, hypokalemia, and metabolic alkalosis, but low serum levels of aldosterone.

Bartter syndrome and Gitelman syndrome are autosomal recessive disorders associated with normal blood pressure, elevations of urinary chloride, metabolic alkalosis, and hypokalemia (see Chapter 531). In Bartter syndrome, patients have a defect in sodium and chloride resorption in the loop of Henle. This leads to excessive urinary losses of sodium and chloride, and as in patients receiving loop diuretics, volume depletion and secondary hyperaldosteronism occur, causing hypokalemia and metabolic alkalosis. Gitelman syndrome is usually milder than Bartter syndrome. Patients have renal sodium and chloride wasting with volume depletion due mutations in the gene encoding the thiazide-sensitive sodium-chloride transporter in the distal tubule. As in patients receiving a thiazide diuretic, affected patients have volume depletion and secondary hyperaldosteronism with hypokalemia and metabolic alkalosis. Children with Gitelman syndrome have hypocalciuria and hypomagnesemia. Some patients with autosomal dominant hypoparathyroidism have hypokalemia and metabolic alkalosis due to impaired sodium and chloride resorption in the loop of Henle. EAST syndrome causes hypokalemia, metabolic alkalosis and hypomagnesemia.

Excessive base intake can cause a metabolic alkalosis. Affected patients do not have a low urine chloride level, unless there is associated volume depletion. In the absence of volume depletion, excess base is rapidly corrected via renal excretion of bicarbonate. Rarely, massive base intake can cause a metabolic alkalosis by overwhelming the kidney’s ability to excrete bicarbonate. This may occur in infants who are given baking soda as a “home remedy” for colic or stomach upset. Each teaspoon of baking soda has 42 mEq of sodium bicarbonate. Infants have increased vulnerability because of a lower GFR, limiting the rate of compensatory renal bicarbonate excretion. A metabolic alkalosis may also occur in patients who receive a large amount of sodium bicarbonate during cardiopulmonary resuscitation. Blood products are anticoagulated with citrate, which is converted into bicarbonate by the liver. Patients who receive large amounts of blood products may have a metabolic alkalosis. Latrogenic metabolic alkalosis can occur as a result of acetate in total parenteral nutrition. Aggressive use of bicarbonate therapy in a child with a lactic acidosis or diabetic ketoacidosis may cause a metabolic alkalosis. This event is especially likely in a patient in whom the underlying cause of the lactic acidosis is successfully corrected (restoration of intravascular volume in a patient with severe dehydration). Once the cause of the lactic acidosis resolves, lactate can be converted by the liver into bicarbonate, which when combined with infused bicarbonate can create a metabolic alkalosis. A similar phenomenon can occur in a child with diabetic ketoacidosis.
because the administration of insulin allows keto acids to be metabolized, producing bicarbonate. However, this phenomenon rarely occurs because of judicious use of bicarbonate therapy in diabetic ketoacidosis and because there are usually significant pretreatment losses of keto acids in the urine, preventing massive regeneration of bicarbonate. Base administration is most likely to cause a metabolic alkalosis in patients who have an impaired ability to excrete bicarbonate in the urine. This impairment occurs in patients with concurrent volume depletion or renal insufficiency.

**Clinical Manifestations**

The symptoms in patients with a metabolic alkalosis are often related to the underlying disease and associated electrolyte disturbances. Children with chloride-responsive causes of metabolic alkalosis often have symptoms related to volume depletion, such as thirst and lethargy. In contrast, children with chloride-unresponsive causes may have symptoms related to hypertension.

Alkalemia causes potassium to shift into the intracellular space, producing a decrease in the extracellular potassium concentration. Alkalemia leads to increased urinary losses of potassium. Increased potassium losses are present in many of the conditions that cause a metabolic alkalosis. Therefore, most patients with a metabolic alkalosis have hypokalemia, and their symptoms may be related to the hypokalemia (see Chapter 55.4).

The symptoms of a metabolic alkalosis are caused by the associated alkalemia. The magnitude of the alkalemia is related to the severity of the metabolic alkalosis and the presence of concurrent respiratory acid–base disturbances. During alkalemia, the ionized calcium concentration decreases as a result of increased binding of calcium to albumin. The decrease in the ionized calcium concentration may cause symptoms of *tetany* (carpopedal spasm).

Arrhythmias are a potential complication of a metabolic alkalosis, and the risk for arrhythmia increases if there is concomitant hypokalemia. Alkalemia increases the risk of digoxin toxicity, and antiarrhythmic medications are less effective in the presence of alkalemia. In addition, alkalemia may decrease cardiac output. A metabolic alkalosis causes a compensatory increase in the Pco₂ by decreasing ventilation. In patients with underlying lung disease, the decrease in ventilatory drive can cause hypoxia. In patients with normal lungs, the hypoventilation seen in severe metabolic alkalosis can cause hypoxia.

**Diagnosis**

Measurement of the urinary chloride concentration is the most helpful test in differentiating among the causes of a metabolic alkalosis. The urine chloride level is low in patients with a metabolic alkalosis resulting from volume depletion, whereas there is a defect in renal handling of chloride. The urine chloride level is superior to the urine sodium level in assessment of volume status in patients with a metabolic alkalosis, because the normal renal response to a metabolic alkalosis is to excrete bicarbonate. Because bicarbonate is negatively charged, it can be excreted only with a cation, usually sodium and potassium. Hence, a patient with a metabolic alkalosis may excrete sodium in the urine despite the presence of volume depletion, which normally causes avid sodium retention. The *urine chloride level is usually a good indicator of volume status, and it differentiates among the chloride-resistant and chloride-responsive causes of a metabolic alkalosis.*

Diuretics and gastric losses are the most common causes of metabolic alkalosis and are usually readily apparent from the patient history. Occasionally, metabolic alkalosis, usually with hypokalemia, may be a clue to the presence of bulimia or surreptitious diuretic use (see Chapter 28). Patients with bulimia have a low urine chloride level, indicating that they have volume depletion as a result of an extrarenal etiology, but there is no alternative explanation for their volume depletion. Surreptitious diuretic use may be diagnosed by obtaining a urine toxicology screen for diuretics. The urine chloride level is increased while a patient is using diuretics but is low when the patient stops taking them. Rarely, children with mild Bartter syndrome or Gitelman syndrome are misdiagnosed as having bulimia or abusing diuretics.

The urine chloride value is always elevated in Bartter syndrome and Gitelman syndrome, and the urine toxicology screen for diuretics has a negative result. Metabolic alkalosis with hypokalemia is occasionally the initial manifestation of cystic fibrosis. An elevated sweat chloride finding is diagnostic.

Patients with a metabolic alkalosis and a high urinary chloride level are subdivided according to blood pressure status. Children with normal blood pressure may have Bartter syndrome or Gitelman syndrome. Excess base administration is another diagnostic possibility, but it is usually apparent from the history. In patients with sodium bicarbonate ingestion (baking soda), which may be unreported by the parent, the metabolic alkalosis usually occurs with significant hypernatremia. In addition, unless volume depletion is superimposed, the metabolic alkalosis from base ingestion resolves itself once the source of base is eliminated.

Measuring serum concentrations of renin and aldosterone differentiates children with a metabolic alkalosis, a high urinary chloride level, and elevated blood pressure. Both renin and aldosterone are elevated in children with either renovascular disease or a renin-secreting tumor. Aldosterone is high and renin is low in patients with adrenal adenomas or hyperplasia and glucocorticoid-remediable aldosteronism. Renin and aldosterone are low in children with Cushing syndrome; Liddle syndrome, licorice ingestion, 17α-hydroxylase deficiency, 1ββ-hydroxylase deficiency, and 11β-hydroxysteroid dehydrogenase deficiency. An elevated 24 hr urine cortisol value is diagnostic of Cushing syndrome, which is suspected from the presence of the other classic features of this disease (see Chapter 577). Elevations of 11-deoxycorticosterone values are seen in 17α-hydroxylase deficiency and 11β-hydroxylase deficiency.

**Treatment**

The approach to treatment of metabolic alkalosis depends on the severity of the alkalosis and the underlying etiology. In children with a mild metabolic alkalosis ([HCO₃⁻] <32), intervention is often unnecessary, although this depends on the specific circumstances. In a child with congenital heart disease who is receiving a stable dose of a loop diuretic, a mild alkalosis does not require treatment. In contrast, intervention may be appropriate in a child with a worsening mild metabolic alkalosis because of nasogastric suction. The presence of a concurrent respiratory acid–base disturbance also influences therapeutic decision making. A patient with a concurrent respiratory acidosis should have some increase in bicarbonate owing to metabolic compensation; thus, the severity of the pH elevation is more important than the bicarbonate concentration. In contrast, a patient with a respiratory alkalosis and a metabolic alkalosis is at risk for severe alkalosis; treatment may be indicated, even if the increase in bicarbonate value is only mild.

Intervention is usually necessary in children with moderate or severe metabolic alkalosis. The most effective approach is to address the underlying etiology. In some children, nasogastric suction may be decreased or discontinued. Alternatively, the addition of a gastric proton pump inhibitor reduces gastric secretion and losses of HCl. Diuretics are an important cause of metabolic alkalosis, and if a change is tolerated, they should be eliminated or the dose reduced. Adequate potassium supplementation or the addition of a potassium-sparring diuretic is also helpful in a child with a metabolic alkalosis from diuretics. Potassium-sparring diuretics not only decrease renal potassium losses but, by blocking the action of aldosterone, also decrease hydrogen ion secretion in the distal nephron, increasing urinary bicarbonate excretion. Many children cannot tolerate discontinuation of diuretic therapy; thus, potassium supplementation and potassium-sparring diuretics are the principal therapeutic approach. Arginine HCl may also be used to treat chloride-responsive metabolic acidosis if sodium or potassium salts are not appropriate. Arginine HCl may raise the serum potassium levels during administration. Rarely, in cases of severe metabolic alkalosis, acetazolamide is an option. A carbonic anhydrase inhibitor, acetazolamide decreases resorption of bicarbonate in the proximal tubule, causing significant bicarbonate loss in the urine. The patient receiving this drug must be monitored closely,
because acetazolamide produces major losses of potassium in the urine and increases fluid losses, potentially necessitating a reduction in dosage of other diuretics.

Most children with a metabolic alkalosis have one of the chloride-responsive etiologies. In these situations, administration of sufficient sodium chloride and potassium chloride to correct the volume deficit and the potassium deficit is necessary to correct the metabolic alkalosis. This approach may not be an option in the child who has volume depletion due to diuretics, because volume repletion may be contraindicated. Adequate replacement of gastric losses of sodium and potassium in a child with a nasogastric tube can minimize or prevent the development of the metabolic alkalosis. With adequate intravascular volume and a normal serum potassium concentration, the kidney is able to excrete the excess bicarbonate within a couple of days.

In children with the chloride-resistant causes of a metabolic alkalosis that are associated with hypertension, volume repletion is contraindicated because it would exacerbate the hypertension and would not repair the metabolic alkalosis. Ideally, treatment focuses on eliminating the excess aldosterone effect. Adrenal adenomas can be resected, licorice intake can be eliminated, and renovascular disease can be repaired. Glucocorticoid-remediable aldosteronism, 17α-hydroxylase deficiency, and 11β-hydroxylase deficiency respond to the administration of glucocorticoids. The mineralocorticoid effect of cortisol in 11β-hydroxysteroid dehydrogenase deficiency can be decreased with the use of spironolactone, which blocks the mineralocorticoid receptor.

In contrast, the metabolic alkalosis in children with Liddle syndrome does not respond to spironolactone; however, either triamterene or amiloride is effective therapy because both agents block the sodium channel that is constitutively active in Liddle syndrome.

In children with Bartter syndrome and Gitelman syndrome, therapy includes oral potassium supplementation and potassium-sparring diuretics. Children with Gitelman syndrome often require magnesium supplementation, whereas children with severe Bartter syndrome often benefit from indomethacin.

**RESPIRATORY ACIDOSIS**

A respiratory acidosis is an inappropriate increase in blood CO₂ (PCO₂). Carbon dioxide is a byproduct of metabolism, and it is removed from the body by the lungs. During a respiratory acidosis, there is a decrease in the effectiveness of CO₂ removal by the lungs. A respiratory acidosis is secondary to either pulmonary disease, such as severe bronchiolitis, or nonpulmonary disease, such as a narcotic overdose. Even though body production of CO₂ can vary, normal lungs are able to accommodate this variation; excess production of CO₂ is not an isolated cause of a respiratory acidosis. With impairment of alveolar ventilation, the rate of body production of CO₂ may affect the severity of the respiratory acidosis, but this is usually not a significant factor.

A respiratory acidosis causes a decrease in the blood pH, but there is normally a metabolic response that partially compensates, minimizing the severity of the acidemia. The acute metabolic response to a respiratory alkalosis occurs within minutes. The metabolic compensation for an acute respiratory acidosis is secondary to titration of acid by nonbicarbonate buffers. This buffering of hydrogen ions causes a predictable increase in the serum bicarbonate concentration: Plasma bicarbonate increases by 1 for each 10 mm Hg increase in the PCO₂ (acute compensation).

With a chronic respiratory acidosis, there is more significant metabolic compensation and, thus, less severe acidemia than in an acute respiratory acidosis with the same increase in PCO₂. During a chronic respiratory acidosis, the kidneys increase acid excretion. This response occurs over 3-4 days and causes a predictable increase in the serum bicarbonate concentration: Plasma bicarbonate increases by 3.5 for each 10 mm Hg increase in the PCO₂ (chronic compensation).

The increase of serum bicarbonate concentration during a chronic respiratory acidosis is associated with a decrease in body chloride. After acute correction of a chronic respiratory acidosis, the plasma bicarbonate continues to be increased, and the patient has a metabolic alkalosis. Because of the chloride deficit, this is a chloride-responsive metabolic alkalosis; it corrects once the patient’s chloride deficit is replaced.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher-than-expected bicarbonate value occurs in the setting of a concurrent metabolic alkalosis, and a lower-than-expected bicarbonate value occurs in the setting of a concurrent metabolic acidoisis. Evaluating whether compensation is appropriate during a respiratory acidosis requires clinical knowledge of the acuity of the process, because the expected compensation is different, depending on whether the process is acute or chronic.

The PCO₂ cannot be interpreted in isolation to determine whether a patient has a respiratory acidosis. A respiratory acidosis is always present if a patient has acidemia and an elevated PCO₂. However, an elevated PCO₂ also occurs as appropriate respiratory compensation for a simple metabolic alkalosis. The patient is alkalemic; this is not a respiratory acidosis. During a mixed disturbance, a patient can have a respiratory acidosis and a normal or even low PCO₂. This condition may occur in a patient with a metabolic acidosis; a respiratory acidosis is present if the patient does not have appropriate respiratory compensation (the PCO₂ is higher than expected from the severity of the metabolic acidosis).

**Etiology and Pathophysiology**

The causes of a respiratory acidosis are either pulmonary or nonpulmonary (Table 55-15). CNS disorders can decrease the activity of the central respiratory center, reducing ventilatory drive. A variety of medications and illicit drugs suppress the respiratory center. The signals from the respiratory center need to be transmitted to the respiratory muscles via the nervous system. Respiratory muscle failure can be secondary to disruption of the signal from the CNS in the spinal cord, the phrenic nerve, or the neuromuscular junction. Disorders directly affecting the muscles of respiration can prevent adequate ventilation, causing a respiratory acidosis.

Mild or moderate lung disease often causes a respiratory alkalosis as a result of hyperventilation secondary to hypoxia or stimulation of lung mechanoreceptors or chemoreceptors. Only more severe lung disease causes a respiratory acidosis. Upper airway diseases, by impairing air entry into the lungs, may decrease ventilation, producing a respiratory acidosis.

Increased production of CO₂ is never the sole cause of a respiratory acidosis, but it can increase the severity of the disease in a patient with decreased ventilation of CO₂. Increased production of CO₂ occurs in patients with fever, hyperthyroidism, excess caloric intake, and high levels of physical activity. Increased respiratory muscle work also increases CO₂ production.

**Clinical Manifestations**

Patients with a respiratory acidosis are often tachypneic in an effort to correct the inadequate ventilation. Exceptions include patients with a respiratory acidosis resulting from CNS depression and patients who are on the verge of complete respiratory failure secondary to fatigue of the respiratory muscles.

The symptoms of respiratory acidosis are related to the severity of the hypercarbia. Acute respiratory acidosis is usually more symptomatic than chronic respiratory acidosis. Symptoms are also increased by concurrent hypoxia or metabolic acidosis. In a patient breathing room air, hypoxia is always present if a respiratory acidosis is present. The potential CNS manifestations of respiratory acidosis include anxiety, dizziness, headache, confusion, asterixis, myoclonic jerks, hallucinations, psychosis, coma, and seizures.

Acidemia, no matter the etiology, affects the cardiovascular system. An arterial pH < 7.2 impairs cardiac contractility and the normal response to catecholamines, in both the heart and the peripheral vasculature. Hypercapnia causes vasodilation, most dramatically in the cerebral vasculature, but hypercapnia produces vasoconstriction of the pulmonary circulation. Respiratory acidosis increases the risk of cardiac arrhythmias, especially in a child with underlying cardiac disease.

Diagnosis

The history and physical findings often point to a clear etiology. For the obtunded patient with poor respiratory effort, evaluation of the CNS is often indicated. This may include imaging studies (CT or MRI) and, potentially, a lumbar puncture for cerebrospinal fluid analysis. A toxicology screen for illicit drugs may also be appropriate. A response to naloxone is both diagnostic and therapeutic. In many of the diseases affecting the respiratory muscles, there is evidence of weakness in other muscles. Strider is a clue that the child may have upper airway disease. Along with a physical examination, a chest radiograph is often helpful in diagnosing pulmonary disease.

In many patients, respiratory acidosis may be multifactorial. A child with bronchopulmonary dysplasia, an intrinsic lung disease, may worsen because of respiratory muscle dysfunction caused by severe hypokalemia resulting from long-term diuretic therapy. Conversely, a child with muscular dystrophy, a muscle disease, may worsen because of aspiration pneumonia.

For a patient with respiratory acidosis, calculation of the gradient between the alveolar oxygen concentration and the arterial oxygen concentration, the A–A \(O_2\) gradient, is useful for distinguishing between poor respiratory effort and intrinsic lung disease. The A–A \(O_2\) gradient is increased if the hypoxemia is caused by intrinsic lung disease (see Chapter 373). Treatment

Respiratory acidosis is best managed by treatment of the underlying etiology. In some instances, the response is very rapid, such as after the administration of naloxone to a patient with a narcotic overdose. In contrast, in the child with pneumonia, a number of days of antibiotic therapy may be required before the respiratory status improves. In many children with a chronic respiratory acidosis, there is no curative therapy, although an acute respiratory illness superimposed on a chronic respiratory condition is usually reversible.

All patients with an acute respiratory acidosis are hypoxic, and therefore need to receive supplemental oxygen. Mechanical ventilation is necessary in some children with a respiratory acidosis. Children with a significant respiratory acidosis caused by a CNS disease usually require mechanical ventilation because such a disorder is unlikely to respond quickly to therapy. In addition, hypercarbia causes cerebral vasodilation, and the increase in intracranial pressure can be dangerous in a child with an underlying CNS disease. Readily reversible CNS depression, such as from a narcotic overdose, may not require mechanical ventilation. Decisions on mechanical ventilation for other patients depend on a number of factors. Patients with severe hypercarbia—\(P_{CO_2} > 75\) mm Hg—usually require mechanical ventilation (see Chapter 71). The threshold for intubation is lower if there is concomitant metabolic acidosis, a slowly responsive underlying disease, or hypoxia that responds poorly to oxygen, or if the patient appears to be tiring and respiratory arrest seems likely.

In patients with a chronic respiratory acidosis, the respiratory drive is often less responsive to hypercarbia and more responsive to hypoxia. Hence, with chronic respiratory acidosis, excessive use of oxygen can blunt the respiratory drive and therefore increase the \(P_{CO_2}\). In these patients, oxygen must be used cautiously.

When possible, it is best to avoid mechanical ventilation in a patient with a chronic respiratory acidosis because extubation is often difficult. However, an acute illness may necessitate mechanical ventilation in a child with a chronic respiratory acidosis. When intubation is necessary, the \(P_{CO_2}\) should be lowered only to the patient’s normal baseline, and this should be done gradually. These patients normally have an elevated serum bicarbonate concentration as a result of metabolic compensation for their respiratory acidosis. A rapid lowering of the \(P_{CO_2}\) can cause a severe metabolic alkalosis, potentially leading to complications, including cardiac arrhythmias, decreased cardiac output, and decreased cerebral blood flow. In addition, prolonged mechanical ventilation at a normal \(P_{CO_2}\) causes the metabolic compensation to resolve. When the patient is subsequently extubated, the patient will no longer benefit from metabolic compensation, causing a more severe acidemia because of the respiratory acidosis.
**RESPIRATORY ALKALOSIS**

A respiratory alkalosis is an inappropriate reduction in the blood CO₂ concentration. This is usually secondary to hyperventilation, initially causing removal of CO₂ to surpass production. Eventually, a new steady state is achieved, with removal equaling production, albeit at a lower CO₂ tension (Pco₂). A respiratory alkalosis that is not the result of hyperventilation may occur in children receiving extracorporeal membrane oxygenation or hemodialysis, with CO₂ lost directly from the blood in the extracorporeal circuit.

With a simple respiratory alkalosis, the pH increases but there is a normal metabolic response that attenuates some of the change in the blood pH. A metabolic response to an acute respiratory alkalosis occurs within minutes, mediated by hydrogen ion release from nonbicarbonate buffers. The metabolic response to an acute respiratory alkalosis is predictable: Plasma bicarbonate falls by 2 for each 10 mm Hg decrease in the Pco₂ (acute compensation).

A chronic respiratory alkalosis leads to more significant metabolic compensation because of the actions of the kidneys, which decrease acid secretion, producing a decrease in the serum bicarbonate concentration. Both the proximal and distal tubules decrease acid secretion. Metabolic compensation for a respiratory alkalosis develops gradually and takes 2-3 days to produce the full effect: Plasma bicarbonate falls by 4 for each 10 mm Hg decrease in the Pco₂ (chronic compensation).

A chronic respiratory alkalosis is the only acid–base disturbance wherein appropriate compensation may normalize the pH, albeit >7.4.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher than expected bicarbonate level occurs in the setting of a concurrent metabolic alkalosis, and a lower than expected bicarbonate level occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory alkalosis requires clinical knowledge of the acuity of the process, because the expected compensation differs according to whether the process is acute or chronic.

A low Pco₂ value does not always indicate a respiratory alkalosis. The Pco₂ also decreases as part of the appropriate respiratory compensation for a metabolic acidosis; this is not a respiratory alkalosis. A metabolic acidosis is the dominant acid–base disturbance in a patient with acidemia and a low Pco₂, even though there could still be a concurrent respiratory alkalosis. In contrast, a respiratory alkalosis is always present in a patient with alkalemia and a low Pco₂. Even a normal Pco₂ value may be consistent with a respiratory alkalosis in a patient with a metabolic alkalosis because an elevated Pco₂ is expected as part of appropriate respiratory compensation for the metabolic alkalosis.

**Etiology and Pathophysiology**

A variety of stimuli can increase the ventilatory drive and cause a respiratory alkalosis (Table 55-16). Arterial hypoxemia or tissue hypoxia stimulates peripheral chemoreceptors to signal the central respiratory center in the medulla to increase ventilation. The resultant greater respiratory effort increases the oxygen content of the blood but depresses the Pco₂. The effect of hypoxemia on ventilation begins when the oxygen saturation decreases to approximately 90% (Po₂ = 60 mm Hg), and hyperventilation increases as hypoxemia worsens. Acute hypoxia is a more potent stimulus for hyperventilation than chronic hypoxia; thus, chronic hypoxia, as occurs in cyanotic heart disease, causes a much-less-severe respiratory alkalosis than an equivalent degree of acute hypoxia. There are many causes of hypoxemia or tissue hypoxia, including primary lung disease, severe anemia, and carbon monoxide poisoning.

The lungs contain chemoreceptors and mechanoreceptors that respond to irritants and stretching and send signals to the respiratory center to increase ventilation. Aspiration or pneumonia may stimulate the chemoreceptors, whereas pulmonary edema may stimulate the mechanoreceptors. Most of the diseases that activate these receptors may also cause hypoxemia and can, therefore, potentially lead to hyperventilation via 2 mechanisms. Patients with primary lung disease may initially have a respiratory alkalosis, but worsening of the disease, combined with respiratory muscle fatigue, often causes respiratory failure and the development of a respiratory acidosis.

**Hyperventilation in the absence of lung disease** occurs with direct stimulation of the central respiratory center. This occurs with CNS diseases, such as meningitis, hemorrhage, and trauma. Central hyperventilation due to lesions, such as infarcts or tumors near the central respiratory center in the midbrain, increases the rate and depth of the respiratory effort. This respiratory pattern portends a poor prognosis because these midbrain lesions are frequently fatal. Systemic processes may cause centrally mediated hyperventilation. Although the exact mechanisms are not clear, liver disease causes a respiratory alkalosis that is usually proportional to the degree of liver failure. Pregnancy causes a chronic respiratory alkalosis, probably mediated by progesterone acting on the respiratory centers. Salicylates, although often causing a concurrent metabolic acidosis, directly stimulate the respiratory center to produce a respiratory alkalosis. The respiratory alkalosis during sepsis is probably due to cytokine release.

**Hyperventilation may be secondary to an underlying disease** that causes pain, stress, or anxiety. In psychogenic hyperventilation or in panic attacks, there is no disease process accounting for the hyperventilation. This disorder may occur in a child who has had an emotionally stressful experience. Alternatively, it may be part of a panic disorder,
Although lung disease is often apparent by history or physical examination, a chest radiograph may detect more subtle disease. The patient with a pulmonary embolism may have benign chest radiograph findings, normal pO₂, and isolated respiratory alkalosis, although hypoxia may eventually occur. Diagnosis of a pulmonary embolism requires a high index of suspicion and should be considered in children without another explanation for respiratory alkalosis, especially if risk factors are present, such as prolonged bed rest and a hypercoagulable state (e.g., nephrotic syndrome or lupus anticoagulant).

### Treatment

There is seldom a need for specific treatment of respiratory alkalosis. Rather, treatment focuses on the underlying disease. Mechanical ventilator settings are adjusted to correct iatrogenic respiratory alkalosis, unless the hyperventilation has a therapeutic purpose (e.g., treatment of increased intracranial pressure).

For the patient with hyperventilation secondary to anxiety, efforts should be undertaken to reassure the child, usually enlisting the parents. Along with reassurance, patients with psychogenic hyperventilation may benefit from benzodiazepines. During an acute episode of psychogenic hyperventilation, rebreathing into a paper bag increases the patient’s PCO₂. Using a paper bag, instead of a plastic bag, allows adequate oxygenation but permits the CO₂ concentration in the bag to increase. The resultant increase in the patient’s PCO₂ decreases the symptoms of the respiratory alkalosis that tend to perpetuate the hyperventilation. Rebreathing should be performed only once other causes of hyperventilation have been eliminated; pulse oximetry during the rebreathing is prudent.

Maintenance and Replacement Therapy
Larry A. Greenbaum

Maintenance intravenous fluids are used in a child who cannot be fed enterally. Along with maintenance fluids, children may require concurrent replacement fluids if they have continued excessive losses, such as may occur with drainage from a nasogastric (NG) tube or with high urine output because of nephrogenic diabetes insipidus. If dehydration is present, the patient also needs to receive deficit replacement (see Chapter 57). A child awaiting surgery may need only maintenance fluids, whereas a child with diarrheal dehydration needs maintenance and deficit therapy and also may require replacement fluids if significant diarrhea continues.

**MAINTENANCE THERAPY**
Children normally have large variations in their daily intake of water and electrolytes. The only exceptions are patients who receive fixed dietary regimens orally, via a gastric tube, or as intravenous total parenteral nutrition (TPN). Healthy children can tolerate significant variations in intake because of the many homeostatic mechanisms that can adjust absorption and excretion of water and electrolytes (see Chapter 55). The calculated water and electrolyte needs that form the basis of maintenance therapy are not absolute requirements. Rather, these calculations provide reasonable guidelines for a starting point to estimate intravenous therapy. Children do not need to be started on intravenous fluids simply because their intake is being monitored in a hospital and they are not taking "maintenance fluids" orally, unless there is a pathologic process present that necessitates high fluid intake.
Maintenance fluids are most commonly necessary in preoperative and postoperative surgical patients; many nonsurgical patients also require maintenance fluids. It is important to recognize when it is necessary to begin maintenance fluids. A normal teenager who is given nothing by mouth (NPO) overnight for a morning procedure does not require maintenance fluids because a healthy adolescent can easily tolerate 12 or 18 hr without oral intake. In contrast, a 6 mo old child waiting for surgery should begin receiving intravenous fluids within 8 hr of the last feeding. Infants become dehydrated more quickly than older patients. A child with obligatory high urine output from nephrogenic diabetes insipidus should begin receiving intravenous fluids soon after being classified as NPO.

Maintenance fluids are composed of a solution of water, glucose, sodium, and potassium. This solution has the advantages of simplicity, long shelf life, low cost, and compatibility with peripheral intravenous administration. Such a solution accomplishes the major objectives of maintenance fluids (Table 56-1). Patients lose water, sodium, and potassium in their urine and stool; water is also lost from the skin and lungs. Maintenance fluids replace these losses, thereby avoiding the development of dehydration and deficiency of sodium or potassium. The glucose in maintenance fluids provides approximately 20% of the normal caloric needs of the patient, prevents the development of starvation ketoacidosis, and diminishes the protein degradation that would occur if the patient received no calories. Glucose also provides added osmotes, thus avoiding the administration of hypotonic fluids that may cause hemolysis.

Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins. This fact is typically not problematic for a patient receiving intravenous fluids for a few days. A patient receiving maintenance intravenous fluids is receiving inadequate calories and will lose 0.5-1% of weight each day. It is imperative that patients not remain on maintenance therapy indefinitely; TPN should be used for children who cannot be fed enterally for more than a few days, especially patients with underlying malnutrition.

Prototypical maintenance fluid therapy does not provide electrolytes such as calcium, phosphorus, magnesium, and bicarbonate. For most patients, this lack is not problematic for a few days, although there are patients who will not tolerate this omission, usually because of excessive losses. A child with renal tubular acidosis wastes bicarbonate in urine. Such a patient will rapidly become acidic unless bicarbonate (or acetate) is added to the maintenance fluids. It is important to remember the limitations of maintenance fluid therapy.

### MAINTENANCE WATER

Water is a crucial component of maintenance fluid therapy because of the obligatory daily water losses. These losses are both measurable (urine, stool) and not measurable (insensible losses from the skin and lungs). Failure to replace these losses leads to a child who is thirsty, uncomfortable, and, ultimately, dehydrated.

The goal of maintenance water is to provide enough water to replace these losses. Although urinary losses are approximately 60% of the total, the normal kidney has the ability to markedly modify water losses, with daily urine volume potentially varying by more than a factor of 20. Maintenance water is designed to provide enough water so that the kidney does not need to significantly dilute or concentrate the urine. It also provides a margin of safety, so that normal homeostatic mechanisms can adjust urinary water losses to prevent overhydration and dehydration. This adaptability obviates the need for absolute precision in determining water requirements. This fact is important, given the absence of absolute accuracy in the formulas for calculation of water needs.

Table 56-2 provides a system for calculating maintenance water on the basis of the patient’s weight and emphasizes the high water needs of smaller, less-mature patients. This approach is reliable, although calculations based on weight do overestimate the water needs of an overweight child, in whom it is better to base the calculations on the lean body weight, which can be estimated by using the 50th percentile of body weight for the child’s height. It is also important to remember that there is an upper limit of 2.4 L/24 hr in adult-sized patients. Intravenous fluids are written as an hourly rate. The formulas in Table 56-3 enable rapid calculation of the rate of maintenance fluids.

### INTRAVENOUS SOLUTIONS

The components of the commonly available solutions are shown in Table 56-4. Normal saline (NS) and Ringer lactate (LR) are isotonic solutions; they have approximately the same tonicity as plasma. Isotonic fluids without glucose are used for the acute correction of intravascular volume depletion (see Chapter 57). The usual choices for maintenance fluid therapy in children are half-normal saline (1/2 NS) and NS. These solutions are available with 5% dextrose (D5) or without dextrose. In addition, they are available with 20 mEq/L of potassium chloride, 10 mEq/L of potassium chloride, or no potassium. A hospital pharmacy can also prepare custom-made solutions with different concentrations of sodium or potassium. In addition, other electrolytes, such as calcium, magnesium, phosphate, acetate, and bicarbonate, can be added to intravenous solutions. Custom-made solutions take time to prepare and are much more expensive than commercial solutions. The use of custom-made solutions is necessary only for patients who have underlying disorders that cause significant electrolyte imbalances.

The use of commercial solutions saves time and expense.

A normal plasma osmolality is 285-295 mOsm/kg. Infusing an intravenous solution peripherally with a much lower osmolality can cause water to move into red blood cells, leading to hemolysis. Thus, intravenous fluids are generally designed to have an osmolality that is either close to 285 or greater (fluids with moderately higher osmolality do not cause problems). Thus, 0.2NS (osmolality = 68) should not be
administered peripherally, but D5 0.2NS (osmolality = 346) or D5 1/2 NS + 20 mEq/L KCl (osmolality = 472) can be administered.

There is controversy about the appropriate sodium content of maintenance fluids, considering the observation that hypotonic fluids may cause hyponatremia, which may have serious sequelae. Hypotonic fluids seem more physiologic given the low sodium content of breast milk and formula. However, hospitalized children often have impaired water excretion, either as a result of volume depletion or of nonosmotic stimuli for antidiuretic hormone (ADH) production (respiratory disease, central nervous system disease, stress, pain, nausea, medications such as narcotics). Hypotonic fluids increase the risk of hyponatremia; 0.2NS is no longer recommended as a standard maintenance fluid and its use is restricted at many hospitals.

**GLUCOSE**

Maintenance fluids usually contain D5, which provides 17 calories/100 mL and nearly 20% of the daily caloric needs. This level is enough to prevent ketone production and helps minimize protein degradation, but the child will lose weight on this regimen. The weight loss is the principal reason why a patient needs to be started on TPN after a few days of maintenance fluids if enteral feedings are still not possible. Maintenance fluids are also lacking in such crucial nutrients as protein, fat, vitamins, and minerals.

**SELECTION OF MAINTENANCE FLUIDS**

D5 1/2 NS + 20 mEq/L KCl is recommended in the child who is NPO and does not have volume depletion or risk factors for nonosmotic ADH production. Children with volume depletion, baseline hyponatremia, or at risk for nonosmotic ADH production (lung infections such as bronchiolitis or pneumonia; central nervous system infection) should receive D5 NS + 20 mEq/L KCl. Surgical patients typically receive isotonic fluids (NS, LR) during surgery and in the recovery room for 6-8 hr postoperatively; the rate is typically approximately two-thirds of the calculated maintenance rate, with dextrose added if clinically indicated. Subsequent maintenance fluids should be D5 NS or LR, with addition of 10-20 mEq/L of KCl based on the serum potassium and the clinical setting. Electrolytes should be measured at least daily in all children receiving more than 50% of maintenance fluids intravenously unless the child is receiving prolonged intravenous fluids (TPN).

These guidelines assume that there is no disease process present that would require an adjustment in either the volume or the electrolyte composition of maintenance fluids. Neonates, and especially premature infants, are outside of the scope of these guidelines given their unique physiology. Children with renal insufficiency may be hyperkalemic or unable to excrete potassium and may not tolerate 10 or 20 mEq/L of potassium. Patients with persistent ADH production because of an underlying disease process (syndrome of inappropriate ADH secretion, congestive heart failure, nephrotic syndrome, liver disease) should receive less than maintenance fluids. Children with meningitis are fluid restricted unless intravascular volume depletion is present (see Chapter 603.1). Treatment is individualized, and careful monitoring is critical.

In children with complicated pathophysiologic derangements, it may be necessary to empirically adjust the electrolyte composition and rate of maintenance fluids on the basis of electrolyte measurements and assessment of fluid balance. In all children, it is critical to carefully monitor weight, urine output, and electrolytes to identify overhydration or underhydration, hyponatremia, and other electrolyte disturbances, and to then adjust the rate or composition of the intravenous solution accordingly.

**VARIATIONS IN MAINTENANCE WATER AND ELECTROLYTES**

The calculation of maintenance water is based on standard assumptions regarding water losses. There are patients, however, in whom these assumptions are incorrect. To identify such situations, it is helpful to understand the source and magnitude of normal water losses. Table 56-5 lists the sources of normal water loss.

Urine is the most important contributor to normal water loss. Insensible losses represent approximately one-third of total maintenance water (40% in infants and closer to 25% in adolescents and adults). Insensible losses are composed of evaporative losses from the skin and lungs that cannot be quantitated. The evaporative losses from the skin do not include sweat, which would be considered an additional (sensible) source of water loss. Stool normally represents a minor source of water loss.

Maintenance water and electrolyte needs may be increased or decreased, depending on the clinical situation. This may be obvious, in the case of the infant with profuse diarrhea, or subtle, in the case of the patient who has decreased insensible losses while receiving mechanical ventilation. It is helpful to consider the sources of normal water and electrolyte losses and to determine whether any of these sources is being modified in a specific patient. It is then necessary to adjust maintenance water and electrolyte calculations. Table 56-6 lists a variety of clinical situations that modify normal water and electrolyte losses. The skin can be a source of very significant water loss, particularly in neonates, especially premature infants, who are under radiant warmers or are receiving phototherapy. Very-low-birthweight infants can have insensible losses of 100-200 mL/kg/24 hr. Burns can result in massive losses of water and electrolytes, and there are specific guidelines for fluid management in children with burns (see Chapter 75). Sweat losses of water and electrolytes, especially in a warm climate, can also be significant. Children with cystic fibrosis have increased sodium losses from the skin. Some children with pseudohypoaldosteronism also have increased cutaneous salt losses.

Fever increases evaporative losses from the skin. These losses are somewhat predictable, leading to a 10-15% increase in maintenance water needs for each 1°C (1.8°F) increase in temperature above 38°C (100.4°F). These guidelines are for a patient with a persistent fever; a 1 hr fever spike does not cause an appreciable increase in water needs.

Tachypnea or a tracheostomy causes a decrease in insensible losses from the lungs and can even lead to water absorption via the lungs; a ventilated patient has a decrease in maintenance water requirements. It may be difficult to quantify the changes that take place in the individual patient in these situations.
REPLACEMENT FLUIDS

The gastrointestinal (GI) tract is potentially a source of considerable water loss. GI water losses are accompanied by electrolytes and thus may cause disturbances in intravascular volume and electrolyte concentrations. GI losses are often associated with loss of potassium, leading to hypokalemia. Because of the high bicarbonate concentration in stool, children with diarrhea usually have a metabolic acidosis, which may be accentuated if volume depletion causes hypoperfusion and a concurrent lactic acidosis. Emesis or losses from an NG tube can cause a metabolic alkalosis (see Chapter 55).

In the absence of vomiting, diarrhea, or NG drainage, GI losses of water and electrolytes are usually quite small. All GI losses are considered excessive, and the increase in the water requirement is equal to the volume of fluid losses. Because GI water and electrolyte losses can be precisely measured, it is possible to use an appropriate replacement solution.

It is impossible to predict the losses for the next 24 hr; it is better to replace excessive GI losses as they occur. The child should receive an appropriate maintenance fluid that does not consider the GI losses. The losses should then be replaced after they occur, with use of a solution with a similar electrolyte concentration as the GI fluid. The losses are usually replaced every 1-6 hr, depending on the rate of loss, with very rapid losses being replaced more frequently.

Diarrhea is a common cause of fluid loss in children. It can cause dehydration and electrolyte disorders. In the unusual patient with significant diarrhea and a limited ability to take oral fluid, it is important to have a plan for replacing excessive stool losses. The volume of stool should be measured, and an equal volume of replacement solution should be given. Data are available on the average electrolyte composition of diarrhea in children (Table 56-7). With use of this information, it is possible to design an appropriate replacement solution. The solution shown in Table 56-7 replaces stool losses of sodium, potassium, chloride, and bicarbonate. Each 1 mL of stool should be replaced by 1 mL of this solution. The average electrolyte composition of diarrhea is just an average, and there may be considerable variation. It is therefore advisable to consider measuring the electrolyte composition of a patient's diarrhea if the amount is especially excessive or if the patient's serum electrolyte levels are problematic.

Loss of gastric fluid, via either emesis or NG suction, is also likely to cause dehydration, in that most patients with either condition have impaired oral intake of fluids. Electrolyte disturbances, particularly hypokalemia and metabolic alkalosis, are also common. These complications can be avoided by judicious use of a replacement solution. The composition of gastric fluid shown in Table 56-8 is the basis for designing a replacement solution.

Patients with gastric losses frequently have hypokalemia, although the potassium concentration of gastric fluid is relatively low. The associated urinary loss of potassium is an important cause of hypokalemia in this situation (see Chapter 55). These patients may need additional potassium either in their maintenance fluids or in their replacement fluids to compensate for prior or ongoing urinary losses. Restoration of the patient's intravascular volume, by decreasing aldosterone synthesis, lessens the urinary potassium losses.

Urine output is normally the largest cause of water loss. Diseases such as renal failure and syndrome of inappropriate ADH secretion can lead to a decrease in urine volume. The patient with oliguria or anuria has a decreased need for water and electrolytes; continuation of maintenance fluids produces fluid overload. In contrast, postobstructive diuresis, the polyuric phase of acute tubular necrosis, diabetes mellitus, and diabetes insipidus increase urine production. To prevent dehydration, the patient must receive more than standard maintenance fluids when urine output is excessive. The electrolyte losses in patients with polyuria are variable. In diabetes insipidus, the urine electrolyte concentration is usually low, whereas children with diseases such as juvenile nephronophthisis and obstructive uropathy usually have increased losses of both water and sodium.

The approach to decreased or increased urine output is similar (Table 56-9). The patient receives fluids at a rate to replace insensible losses. This is accomplished by a rate of fluid administration that is 25-40% of the normal maintenance rate, depending on the patient's age. Replacing insensible losses in the anuric child will theoretically maintain an even fluid balance, with the caveat that 25-40% of the normal maintenance rate is only an estimate of insensible losses. In the individual patient, this rate is adjusted on the basis of monitoring of the patient's weight and volume status. Most children with renal insufficiency receive little or no potassium because the kidney is the principal site of potassium excretion.

For the oliguric child, it is important to add a urine replacement solution to prevent dehydration. This issue is especially important in the patient with acute renal failure, in whom output may increase slowly, potentially leading to volume depletion and worsening of renal failure if the patient remains on only insensible fluids. A replacement solution of D5/2NS is usually appropriate initially, although its composition may have to be adjusted if urine output increases significantly.

Most children with polyuria (except in diabetes mellitus; see Chapter 589) should be started on replacement of insensible fluid plus urine losses. This approach avoids the need to attempt to calculate the volume of urine output that is "normal" so that the patient can be given replacement fluid for the excess. In these patients, urine output is, by definition, excessive, and it is important to measure the sodium and potassium concentrations of the urine to help in formulating the urine replacement solution.

Surgical drains and chest tubes can produce measurable fluid output. These fluid losses should be replaced when they are significant. They can be measured and replaced with an appropriate replacement solution. Third space losses, which manifest as edema and ascites, are due to a shift of fluid from the intravascular space into the interstitial space.

Although these losses cannot be quantitated easily, third space losses can be large and may lead to intravascular volume depletion, despite

the patient’s weight gain. Replacement of third space fluid is empirical but should be anticipated in patients who are at risk, such as children who have burns or abdominal surgery. Third space losses and chest tube output are isotonic; thus, they usually require replacement with an isotonic fluid, such as NS or LR. Adjustments in the amount of replacement fluid for third space losses are based on continuing assessment of the patient’s intravascular volume status. Protein losses from chest tube drainage can be significant, occasionally necessitating that 5% albumin be used as a replacement solution.

Dehydration, most often caused by gastroenteritis, is a common problem in children. Most cases can be managed with oral rehydration (see Chapter 340). Even children with mild to moderate hypotonic or hypernatremic dehydration can be managed with oral rehydration.

**CLINICAL MANIFESTATIONS**

The first step in caring for the child with dehydration is to assess the degree of dehydration (Table 57-1), which dictates both the urgency of the situation and the volume of fluid needed for rehydration. The infant with mild dehydration (3-5% of body weight dehydrated) has few clinical signs or symptoms. The infant may be thirsty; the alert parent may notice a decline in urine output. The history is most helpful. The infant with moderate dehydration has clear physical signs and symptoms. Intravascular space depletion is evident from an increased heart rate and reduced urine output. This patient needs fairly prompt intervention. The infant with severe dehydration is gravely ill. The decrease in intravascular volume may cause rapid heart rate and reduced urine output. The history is most helpful. The infant with severe dehydration should initially receive intravenous therapy. For older children and adults, mild, moderate, or severe dehydration represents a lower percentage of body weight lost. This difference occurs because water accounts for a higher percentage of body weight in infants (see Chapter 55). Clinical assessment of dehydration is only an estimate; thus, the patient must be continually reevaluated during therapy. The degree of dehydration is underestimated in hypernatremic dehydration because the movement of water from the intracellular space to the extracellular space helps preserve the intravascular volume.

</table>

The history usually suggests the etiology of the dehydration and may predict whether the patient will have a normal sodium concentration (isotonic dehydration), hypotonic dehydration, or hypernatremic dehydration. The neonate with dehydration due to poor intake of breast milk often has hypernatremic dehydration. Hypernatremic dehydration is likely in any child with losses of hypotonic fluid and poor water intake, such as may occur with diarrhea, and poor oral intake because of anorexia or emesis. Hypotonic dehydration occurs in the child with diarrhea who is taking in large quantities of low-salt fluid, such as water or formula.

Some children with dehydration are appropriately thirsty, but in others the lack of intake is part of the pathophysiology of the dehydration. Even though decreased urine output is present in most children with dehydration, good urine output may be deceivingly absent if a child has an underlying renal defect, such as diabetes insipidus or a salt-wasting nephropathy, or in infants with hypernatremic dehydration.

Physical examination findings are usually proportional to the degree of dehydration. Parents may be helpful in assessment of the child for the presence of sunken eyes, because this finding may be subtle. Pinching and gently twisting the skin of the abdominal or thoracic wall detects tenting of the skin (turgor, elasticity). Tented skin remains in a pinched position rather than springing quickly back to normal. It is difficult to properly assess tenting of the skin in premature infants or severely malnourished children. Activation of the sympathetic nervous system causes tachycardia in children with intravascular volume depletion; diaphoresis may also be present. Postural changes in blood pressure are often helpful for evaluating and assessing the response to therapy in children with dehydration. Tachypnea in children with dehydration may be present secondary to a metabolic acidosis from stool losses of bicarbonate or due to lactic acidosis from shock (see Chapter 70).

**LABORATORY FINDINGS**

Several laboratory findings are useful for evaluating the child with dehydration. The serum sodium concentration determines the type of dehydration. Metabolic acidosis may be a result of stool bicarbonate losses in children with diarrhea, secondary renal insufficiency, or lactic acidosis from shock. The anion gap is useful for differentiating among the various causes of a metabolic acidosis (see Chapter 55). Emesis or nasogastric losses usually cause a metabolic alkalosis. The serum potassium concentration may be low as a result of diarrheal losses. In children with dehydration as a result of emesis, gastric potassium losses, metabolic alkalosis, and urinary potassium losses all contribute to hypokalemia. Metabolic acidosis, which causes a shift of potassium out of cells, and renal insufficiency may lead to hyperkalemia. A combination of mechanisms may be present; thus, it may be difficult to predict the child's acid–base status or serum potassium level from the history alone.

The blood urea nitrogen (BUN) value and serum creatinine concentration are useful in assessing the child with dehydration. Volume depletion without parenchymal renal injury may cause a disproportionate increase in the BUN with little or no change in the creatinine concentration. This condition is secondary to increased passive resorption of urea in the proximal tubule as a result of appropriate renal conservation of sodium and water. The increase in the BUN with moderate or severe dehydration may be absent or blunted in the child with poor protein intake, because urea production depends on protein degradation. The BUN may be disproportionately increased in the child with increased urea production, as occurs with a gastrointestinal bleed or with the use of glucocorticoids, which increase catabolism. A significant elevation of the creatinine concentration suggests renal insufficiency, although a small, transient increase can occur with dehydration. Acute tubular necrosis (acute kidney injury) (see Chapter 535) because of volume depletion is the most common etiology of renal insufficiency in a child with volume depletion, but occasionally the child may have previously undetected chronic renal insufficiency or an alternative explanation for the acute renal failure. Renal vein thrombosis is a well-described sequela of severe dehydration in infants;
possible findings include thrombocytopenia and hematuria (see Chapter 519.7).

Hemoconcentration from dehydration causes increases in hematocrit, hemoglobin, and serum proteins. These values normalize with rehydration. A normal hemoglobin concentration during acute dehydration may mask an underlying anemia. A decreased albumin level in a dehydrated patient suggests a chronic disease, such as malnutrition, nephrotic syndrome, or liver disease, or an acute process, such as capillary leak. An acute or chronic protein-losing enteropathy may also cause a low serum albumin concentration.

**CALCULATION OF THE FLUID DEFICIT**

Determining the fluid deficit necessitates clinical determination of the percentage of dehydration and multiplication of this percentage by the patient's weight; a child who weighs 10 kg and is 10% dehydrated has a fluid deficit of 1 L.

**APPROACH TO SEVERE DEHYDRATION**

The child with dehydration needs acute intervention to ensure that there is adequate tissue perfusion. This resuscitation phase requires rapid restoration of the circulating intravascular volume and treatment of shock with an isotonic solution, such as normal saline (NS) or Ringer lactate (LR) (see Chapter 70). The child is given a fluid bolus, usually 20 mL/kg of the isotonic fluid, over approximately 20 min. The child with severe dehydration may require multiple fluid boluses and may need to receive the boluses as fast as possible. In a child with a known or probable metabolic alkalosis (the child with isolated vomiting), LR should not be used because the lactate would worsen the alkalosis.

Colloids, such as blood, 5% albumin, and plasma, are rarely needed for fluid boluses. A crystalloid solution (NS or LR) is satisfactory, with both less infectious risk and lower cost. Blood is obviously indicated in the child with significant anemia or acute blood loss. Plasma is useful for children with a coagulopathy. The child with hypoalbuminemia may benefit from 5% albumin, although there is evidence that albumin infusions increase mortality in adults. The volume and the infusion rate for colloids are generally modified compared with crystalloids (see Chapters 473).

The initial resuscitation and rehydration phase is complete when the child has an adequate intravascular volume. Typically, the child shows clinical improvement, including a lower heart rate, normalization of blood pressure, improved perfusion, better urine output, and a more alert affect.

With adequate intravascular volume, it is appropriate to plan the fluid therapy for the next 24 hr. A general approach is outlined in Table 57-2, with the caveat that there are many different approaches to correcting dehydration. In isonatremic or hyponatremic dehydration, the entire fluid deficit is corrected over 24 hr; a slower approach is used for hypernatremic dehydration (discussed later). The volume of isotonic fluids that the patient has received is subtracted from this total. The remaining fluid volume is then administered over 24 hr. The potassium concentration may need to be decreased or, less commonly, increased, depending on the clinical situation. Potassium is not usually included in the intravenous fluids until the patient voids and normal renal function is documented via measurement of BUN and creatinine. Children with significant ongoing losses need to receive an appropriate replacement solution (see Chapter 56).

**MONITORING AND ADJUSTING THERAPY**

The formulation of a plan for correcting a child's dehydration is only the beginning of management. All calculations in fluid therapy are only approximations. This statement is especially true for the assessment of percentage dehydration. It is equally important to monitor the patient during treatment and to modify therapy on the basis of the clinical situation. Table 57-3 lists the cornerstones of patient monitoring. The patient's vital signs are useful indicators of intravascular volume status. The child with decreased blood pressure and an increased heart rate will probably benefit from a fluid bolus. Central venous pressure is an excellent indicator of fluid status in the critically ill child with shock.

The patient's intake and output are critically important in the dehydrated child. The child who, after 8 hr of therapy, has more output than input because of continuing diarrhea needs to be started on a replacement solution. See the guidelines in Chapter 56 for selecting an appropriate replacement solution. Urine output is useful for evaluating the success of therapy. Good urine output indicates that rehydration has been successful.

Signs of dehydration on physical examination suggest the need for continued rehydration. Signs of fluid overload, such as edema and pulmonary congestion, are present in the child who is overhydrated. An accurate daily weight measurement is critical for the management of the dehydrated child. There should be a gain in weight during successful therapy.

Measurement of serum electrolyte levels at least daily is appropriate for any child who is receiving intravenous rehydration. Such a child is at risk for sodium, potassium, and acid–base disorders. It is always important to look at trends. For instance, a sodium value of 144 mEq/L is normal; but if the sodium concentration was 136 mEq/L 12 hr earlier, then there is a distinct risk that the child will be hypernatremic in 12 or 24 hr. It is advisable to be proactive in adjusting fluid therapy.

Both hypokalemia and hyperkalemia are potentially serious (see Chapter 55). Because dehydration can be associated with acute renal failure and hyperkalemia, potassium is withheld from intravenous fluids until the patient has voided. The potassium concentration in the patient's intravenous fluids is not rigidly prescribed. Rather, the patient's serum potassium level and underlying renal function are used to modify potassium delivery. The patient with an elevated creatinine value and a potassium level of 5 mEq/L does not receive any potassium until the serum potassium level decreases. Conversely, the patient with a potassium level of 2.5 mEq/L may require additional potassium.

Metabolic acidosis can be quite severe in dehydrated children. Although normal kidneys eventually correct this problem, a child with renal dysfunction may be unable to correct a metabolic acidosis, and a portion of the patient's intravenous sodium chloride may have to be replaced with sodium bicarbonate or sodium acetate.

The serum potassium level is modified by the patient's acid–base status. Acidosis increases serum potassium by causing intracellular potassium to move into the extracellular space. Thus, as acidosis is corrected, the potassium concentration decreases. Again, it is best to anticipate this problem and to monitor the serum potassium concentration and adjust potassium administration appropriately.
HYPONATREMIC DEHYDRATION
The pathogenesis of hyponatremic dehydration usually involves a combination of sodium and water loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and the lost fluid contains sodium. Most fluid that is lost has a lower sodium concentration, so patients with only fluid loss would have hyponatremia. Diarrhea has, on average, a sodium concentration of 50 mEq/L. Replacing diarrheal fluid with water, which has almost no sodium, causes a reduction in the serum sodium concentration. The volume depletion stimulates synthesis of antidiuretic hormone, resulting in reduced renal water excretion. Hence, the body’s usual mechanism for preventing hyponatremia, renal water excretion, is blocked. The risk of hyponatremia is further increased if the volume depletion is a result of loss of fluid with a higher sodium concentration, as may occur with renal salt wasting, third space losses, or diarrhea with high sodium content (cholera).

The initial goal in treating hyponatremia is correction of intravascular volume depletion with isotonic fluid (NS or LR). An overly rapid (>12 mEq/L over the first 24 hr) or overcorrection in the serum sodium concentration (>135 mEq/L) is associated with an increased risk of central pontine myelinolysis (see Chapter 55). Most patients with hyponatremic dehydration do well with the same basic strategy that is outlined in Table 57-2. Again, potassium delivery is adjusted according to the initial serum potassium level and the patient’s renal function. Potassium is not given until the patient voids.

The patient’s sodium concentration is monitored closely to ensure appropriate correction, and the sodium concentration of the fluid is adjusted accordingly. Patients with ongoing losses require an appropriate replacement solution (see Chapter 56). Patients with neurologic symptoms (seizures) as a result of hyponatremia need to receive an acute infusion of hypertonic (3%) saline to increase the serum sodium concentration rapidly (see Chapter 55).

HYPERNATREMIC DEHYDRATION
Hyponatremic dehydration is the most dangerous form of dehydration because of complications of hypernatremia and of therapy. Hypernatremia can cause serious neurologic damage, including central nervous system hemorrhages and thrombosis. This damage appears to be secondary to the movement of water from the brain cells into the hypertonic extracellular fluid, causing brain cell shrinkage and tearing blood vessels within the brain (see Chapter 55).

The movement of water from the intracellular space to the extracellular space during hypernatremic dehydration partially protects the intravascular volume. Unfortunately, because the initial manifestations are milder, children with hypernatremic dehydration are often brought for medical attention with more profound dehydration.

Children with hypernatremic dehydration are often lethargic, and they may be irritable when touched. Hyponatremia may cause fever, hypotension, and hyperreflexia. More severe neurologic symptoms may develop if cerebral bleeding or thrombosis occurs.

Overly rapid treatment of hypernatremic dehydration may cause significant morbidity and mortality. Idiogenic osmoles are generated within the brain during the development of hypernatremia. These idiogenic osmoles increase the osmolality within the cells of the brain, providing protection against brain cell shrinkage caused by movement of water out of the cells and into the hypertonic extracellular fluid. They dissipate slowly during the correction of hypernatremia. With overly rapid lowering of the extracellular osmolality during the correction of hypernatremia, an osmotic gradient may be created that causes water movement from the extracellular space into the cells of the brain, producing cerebral edema. Symptoms of the resultant cerebral edema can range from seizures to brain herniation and death.

To minimize the risk of cerebral edema during the correction of hypernatremic dehydration, the serum sodium concentration should not decrease by >12 mEq/L every 24 hr. The deficits in severe hypernatremic dehydration may need to be corrected over 2-4 days (Table 57-4).

The initial resuscitation of hypernatremic dehydration requires restoration of the intravascular volume with NS. LR should not be used because it is more hypotonic than NS and may cause too rapid a decrease in the serum sodium concentration, especially if multiple fluid boluses are necessary.

To avoid cerebral edema during correction of hypernatremic dehydration, the fluid deficit is corrected slowly. The rate of correction depends on the initial sodium concentration (see Table 57-4). There is no general agreement on the choice or the rate of fluid for correcting hypernatremic dehydration. The choice and the rate of fluid administration are not nearly as important as vigilant monitoring of the serum sodium concentration and adjustment of the therapy according to the result (see Table 57-4). The rate of decrease of the serum sodium concentration is roughly related to the “free water” delivery, although there is considerable variation between patients. Free water is water without sodium. NS contains no free water, half-NS (½NS) is 50% free water, and water is 100% free water. Smaller patients, to achieve the same decrease in the sodium concentration, tend to need higher amounts of free water delivery per kilogram because of higher insensible fluid losses. Five percent dextrose (D5) with ½NS is usually an appropriate starting solution for a patient with hypernatremic dehydration. Some patients, especially infants with ongoing high insensible water losses, may need to receive D5 2N or NS, which should be used with great caution and constant monitoring. Others require D5 0.5 NS. A child with dehydration as a result of pure free water loss, as usually occurs with diabetes insipidus, usually needs a more hypotonic fluid than a child with depletion of both sodium and water due to diarrhea.

Adjustment in the sodium concentration of the intravenous fluid is the most common approach to modifying the rate of decrease in the serum concentration (see Table 57-4). For difficult-to-manage patients with severe hypernatremia, having 2 intravenous solutions (e.g., D5 ½ NS and D5 NS, both with the same concentration of potassium) at the bedside can facilitate this approach by allowing for rapid adjustments of the rates of the 2 fluids. If the serum sodium concentration decreases too rapidly, the rate of D5 NS can be increased and the rate of D5 ½ NS can be decreased by the same amount. Adjustment in the total rate of fluid delivery is another approach to modifying free water delivery. For example, if the serum sodium concentration is decreasing too slowly, the rate of the intravenous fluid can be increased, thereby increasing the delivery of free water. There is limited flexibility in modifying the rate of the intravenous fluid because patients generally should receive 1.25-1.5 times the normal maintenance fluid rate. Nevertheless, in some situations, it can be a helpful adjustment.

Because increasing the rate of the intravenous fluid increases the rate of decline of the sodium concentration, signs of volume depletion are

**Follow-up actions:**
- Adjust fluid on basis of clinical status and serum sodium concentration.
- Signs of volume depletion: administer normal saline (20 mL/kg).
- Sodium decreases too rapidly: increase sodium concentration of intravenous fluid.
- Sodium decreases too slowly: decrease sodium concentration of intravenous fluid.
- Increase rate of intravenous fluid.
- Replace ongoing losses as they occur.
treated with additional isotonic fluid boluses. The serum potassium concentration and the level of renal function dictate the potassium concentration of the intravenous fluid; potassium is withheld until the patient voids. Patients with hypernatremic dehydration need an appropriate replacement solution if they have ongoing, excessive losses (see Chapter 56).

Seizures are the most common manifestation of cerebral edema from an overly rapid decrease of the serum sodium concentration during correction of hypernatremic dehydration. Signs of increased intracranial pressure or impending herniation may develop quite rapidly (see Chapter 68). Acutely, increasing the serum concentration via an infusion of 3% sodium chloride can reverse the cerebral edema. Each 1 mL/kg of 3% sodium chloride increases the serum sodium concentration by approximately 1 mEq/L. An infusion of 4 mL/kg often results in resolution of the symptoms. This strategy is similar to that used for treating symptomatic hyponatremia (see Chapter 55).

In patients with severe hypernatremia, oral fluids must be used cautiously. Infant formula, because of its low sodium concentration, has a high free water content, and especially if added to intravenous therapy, it may contribute to a rapid decrease in the serum sodium concentration. Less hypotonic fluid, such as an oral rehydration solution, may be more appropriate initially (see Chapter 340). If oral intake is allowed, its contribution to free water delivery must be taken into account, and adjustment in the intravenous fluid is usually appropriate. Judicious monitoring of the serum sodium concentration is critical.

The role of genetic factors in drug disposition and response, pharmacogenetics, has resulted in many examples of how variations in human genes can lead to interindividual differences in pharmacokinetics and drug response at the level of individual patients. Pharmacogenetic variability contributes to the broad range of drug responses observed in children at any given age or developmental stage; it is expected that children will benefit from the promise of personalized medicine—identifying the right drug for the right patient at the right time (Fig. 59-1). Numerous maturational processes occur from birth through adolescence such that utilization of information resulting from the Human Gene Project and related initiatives must take into account the changing patterns of gene expression that occur over development to improve pharmacotherapeutics in children.

**PHARMACOGENETICS, PHARMACOGENOMICS, AND THE CONCEPT OF PERSONALIZED MEDICINE**

The terms pharmacogenomics and pharmacogenetics tend to be used interchangeably, and precise, consensus definitions are often difficult to determine. Pharmacogenetics classically is defined as the study or clinical testing of genetic variations that give rise to interindividual differences in the response to drugs. The earliest examples of pharmacogenetic traits include specific adverse drug reactions, such as unusually prolonged respiratory muscle paralysis caused by succinylcholine, hemolysis associated with antimalarial therapy, and isoniazid-induced neurotoxicity, all of which are a consequence of inherited variations in enzyme activity. The importance of pharmacogenetic differences has become better understood and is exemplified by the fact that the half-lives of several drugs are more similar in monozygotic twins than in dizygotic twins. However, it is important to note that in addition to pharmacogenetic differences, environmental factors (diet, smoking status, concomitant drug or toxicant exposure), physiologic variables (age, sex, disease, pregnancy), and patient compliance all contribute to variations in drug metabolism and response. Likewise, ethnicity is another potential genetic determinant of drug variability. For example, Chinese patients who are HLA-B*1502-positive and white patients who are positive for HLA-A*3101 have an increased risk of carbamazepine-induced Stevens-Johnson syndrome; white patients who are HLA-B*5701-positive have an increased risk of hypersensitivity to abacavir (Table 59-1).

**Pharmacogenomics** represents the marriage of pharmacology and genomics, and can be defined as the broader application of genome-wide technologies and strategies to identify both disease processes that represent new targets for drug development and factors predictive of efficacy and risk of adverse drug reactions.

**Pharmacokinetics** describes temporal aspects of what the body does to a drug. It is often studied in conjunction with pharmacodynamics, which explores what a drug does to the body (see Chapter 60). The pharmacokinetic properties of a drug are determined by the genes that control the drug's disposition in the body (absorption, distribution, metabolism, excretion). Drug metabolizing enzymes and drug transporters play a particularly important role in this process (Table 59-2), and the functional consequences of genetic variations in many drug metabolizing enzymes have been described between subjects of both similar and different ethnic groups. The most common clinical manifestation of pharmacogenetic variability in drug biotransformation is an increased risk of concentration-dependent toxicity as a result of reduced clearance and consequent drug accumulation. On the other hand, rapid metabolism can lead to accumulation of a toxic metabolite, as has been reported for the hepatic conversion of codeine to morphine in 4 children ages 2-5 yr who received codeine for pain after tonsillectomy and adenoidectomy. This variant pharmacokinetics resulted in 3 deaths and 1 near-death from respiratory depression. As a result of these concerns, physicians are reminded to prescribe any drug at the lowest effective dose, for the shortest time, and only on an as-needed basis.

An equally important manifestation of this variability is lack of efficacy resulting from variations in metabolism of prodrugs. The pharmacogenetics of drug receptors and other target proteins involved in signal transduction or disease pathogenesis can also be expected to contribute significantly to interindividual variability in drug disposition and response.

**Therapeutic drug monitoring** programs recognize that all patients are unique and that the serum concentration-time data for an individual patient theoretically can be used to optimize pharmacotherapy. These programs have been the earliest application of personalized medicine; however, routine therapeutic drug monitoring does not necessarily translate to improved patient outcome in all situations.

The concept of personalized medicine is based on the premise that the wealth of information accompanying the application of genomic technologies to patient-related problems will allow for (1) stratification of patient populations according to their response to a particular medication (e.g., lack of drug efficacy or excessive toxicity), and (2) stratification of diseases into specific subtypes that are categorized according to genomic criteria and by response to particular treatments.

**DEFINITION OF PHARMACOGENETIC TERMS**

Genetic polymorphisms (variations) result when copies of a specific gene present within a population do not have identical nucleotide sequences. The term **allele** refers to one of a series of alternative DNA sequences for a particular gene. In humans, there are 2 copies of every gene. An individual's genotype for a given gene is determined by the set of alleles that the individual possesses. The most common form of genetic variation involves a single base change at a given location, referred to as a **single-nucleotide polymorphism (SNP)** (see Chapter 81). At the other end of the spectrum are **copy number variations**, which refer to the deletion or duplication of identical or near identical DNA sequences that may be thousands to millions of bases in size. Copy number variations occur less frequently than SNPs, but may constitute 0.5-1% of an individual's genome, and thereby contribute significantly to phenotypic variation. **Haplotypes** are collections of SNPs and other allelic variations that are located close to one another and when inherited together these create a catalog of haplotypes, or **HapMap**. When the alleles at a particular gene locus on both chromosomes are identical, a **homozygous** state exists, whereas the term **heterozygous** refers to the situation in which different alleles are present at the same gene locus. The term **genotype** refers to an individual's
Our current understanding of pharmacogenetic principles involves enzymes responsible for drug biotransformation. Individuals are classified as being “fast,” “rapid,” or “extensive” metabolizers at one end of the spectrum, and “slow” or “poor” metabolizers at the other end of the continuum. This may or may not also include an “intermediate” metabolizer group, depending on the particular enzyme. With regard to biotransformation, children are more complex than adults as fetuses differ from that observed in adults (e.g., developmental stages at which functional activity is acquired after birth). Furthermore, there may be discrete periods during childhood in which the genotype-phenotype relationship may differ from that observed in adults (e.g., developmental stages at which enzyme activity appears to be greater in children than in adults). (Adapted from Leeder JS: Translating pharmacogenetics and pharmacogenomics into drug development for clinical pediatric and beyond. Drug Discov Today 9:567–573, 2004.) and newborns may be phenotypically “slow” or “poor” metabolizers for certain drug-metabolizing pathways because of their stage of development, and may acquire a phenotype consistent with their genotype at some point later in the developmental process as they mature. Examples of drug-metabolizing pathways that are significantly affected by ontogeny include glucuronidation and some of the cytochrome P450 (CYP) activities (see Chapters 60, 96, and 97). It is also apparent that not all infants acquire drug metabolism activity at the same rate. This is attributable to interactions between genetics and environmental factors. Interindividual variability in the trajectory (i.e., rate and extent) of acquired drug biotransformation capacity may be considered a developmental phenotype (Fig. 59–2), and it helps to explain the considerable variability in some CYP activities observed immediately after birth.

**Pharmacogenetic, Pharmacogenomic, and Pharmacoproteomic Tools**

Several genotyping platforms are approved by the Food and Drug Administration and are beginning to enter the clinical arena. The Roche AmpliChip CYP450 Test was the first such device to receive FDA.
approval, and many additional products have become available (https://www.pharmgkb.org/views/viewGeneticTests.action). In general, applications are limited to 1 or 2 genes, such as CYP2C9 and VKORC1 genotyping to guide warfarin therapy or genotyping of UGT1A1 to reduce the risk of irinotecan toxicity. A more comprehensive chip that covers >90% of the absorption, distribution, metabolism, and excretion markers as defined by the PharmaADME group (http://pharmaadme.org) is available for drug development and research purposes, and the National Institute of General Medical Sciences–sponsored Pharmacogenomics Research Network has developed a list of high-priority genes of interest (http://pgrn.org/download/attachments/131165/PGRN-seq%20Gene%20List%2010-15-12%20Scherer%20Genes.pdf?version=1&modificationDate=1350681059000&api=2).

In contrast to pharmacogenetic studies that typically target single genes, pharmacogenomic analyses are considerably broader in scope and focus on complex and highly variable drug-related phenotypes with targeting of many genes. Genomewide genotyping technologies have progressed beyond "SNP chips" to evaluate genetic variation at more than 1 million sites throughout an individual genome for SNP and copy number variation analyses to include massively parallel “next-generation sequencing” technologies. Genomewide association studies have been conducted in several pediatric settings, acute lymphoblastic leukemia, and pediatric inflammatory bowel disease. One goal of this type of study is to identify novel genes involved in disease pathogenesis that can lead to new therapeutic targets. Genomewide association studies are also being applied to identify genetic associations with response to drugs, such as warfarin and clopidogrel, and risk for drug-induced toxicity, including statin-induced myopathy and flucloxacinil hepatotoxicity. The "Manhattan plot," a form of data presentation for genomewide association studies, is common in many medical journals (Fig. 59-3A). Next-generation sequencing is being applied to rapidly diagnose mendelian disorders and pathologies thought to have a genetic origin when all other diagnostic approaches have been exhausted.

Investigating differential gene expression before and after drug exposure has the potential to correlate gene expression with variable drug responses and possibly uncover the mechanisms of tissue-specific drug toxicities. These types of studies use microarray technology or RNA-Seq (based on next-generation sequencing technologies) to monitor global changes in expression of thousands of genes (the transcriptome) simultaneously. The underlying hypothesis of these global

gene profiling studies is that the measured signal intensity for each
gene transcript represents its relative expression level. RNA-Seq allows
absolute quantitation of gene expression, as well as detection of alterna-
tive splicing events. Gene expression profiling data are used to improve
disease classification and risk stratification, and are utilized commonly
in oncology. This approach was used to address treatment resistance
in acute lymphoblastic leukemia, and has provided clinically relevant
insights into the mechanistic basis of drug resistance and the genomic
basis of interindividual variability in drug response. Subsets of tran-
scripts, or gene expression “signatures,” are being investigated as poten-
tial prognostic indicators for identifying patients at risk for treatment
failure (Fig. 59-3).

Proteomic studies use many different techniques to detect, quantify,
and identify proteins in a sample (expression proteomics), and to

characterize protein function in terms of activity and protein–protein or protein–nucleic acid interactions (functional proteomics). Two-dimensional electrophoresis coupled with mass spectral detection is the mainstay of expression proteomics. Protein "spots" of interest are "picked," digested with a proteolytic enzyme such as trypsin, and identified by mass spectrometry. The data generated are compared with theoretically derived peptide mass databases for protein identification.

Metabolomics and metabonomics utilize sophisticated analytical platforms, such as nuclear magnetic resonance spectroscopy and liquid or gas chromatography coupled with mass spectral detection, to measure the concentrations of all small molecules present in a sample. Metabolomics refers to the study of the complete set of low-molecular-weight molecules (metabolites) present in a living system (cell, tissue, organ or organism) at a particular developmental or pathological state. Metabonomics is defined as the study of how the metabolic profile of biological systems changes in response to alterations because of physiologic stimuli, toxic exposures, dietary changes, etc. Pharmacometabonomics has been defined as "the prediction of the outcome, efficacy or toxicity, of a drug or xenobiotic intervention in an individual based on a mathematical model of preintervention metabolite signatures." In the future, integrating metabolomics with pharmacogenomics and transcriptomics will result in a more "systems-based" understanding of cellular processes, especially in the context of drug efficacy and toxicity.

DEVELOPMENTAL PHARMACOGENETICS OF DRUG BIOTRANSFORMATION: APPLICATIONS TO PEDIATRIC DRUG THERAPY PRACTICE

The major consequence of pharmacogenetic polymorphisms in drug metabolizing enzymes is concentration-dependent toxicity caused by impaired drug clearance. In certain cases, reduced conversion of prodrug to therapeutically active compounds is also of clinical importance (see Table 59-2). Chemical modification of drugs via biotransformation reactions generally results in termination of biologic activity through decreased affinity for receptors or other cellular targets as well as more rapid elimination from the body. The process of drug biotransformation can be very complex, but is characterized by 3 important features. First is the concept of broad substrate specificity—a single
isozyme may metabolize a large variety of chemically diverse compounds. Second, many different enzymes may be involved in the biotransformation of a single drug (enzyme multiplicity). Finally, a given drug may undergo several different types of reactions. One example of this product multiplicity occurs with racemic warfarin, where at least 7 different hydroxylated metabolites are produced by different CYP isoforms.

**Drug biotransformation** reactions are conveniently classified into 2 main types, phase I and phase II reactions, which occur sequentially and serve to terminate biologic activity and enhance elimination (see Chapter 60). Phase I reactions introduce or reveal (via oxidation, reduction, or hydrolysis) a functional group within the substrate drug molecule that serves as a site for a phase II conjugation reaction. Phase II reactions involve conjugation with endogenous substrates, such as acetate, glucuronic acid, glutathione, glycine, and sulfate. These reactions further increase the polarity of an intermediate metabolite, make the compound more water soluble and thereby enhance its renal excretion. Interindividual variability in drug biotransformation activity (for both phase I and phase II reactions) is a consequence of the complex interplay among genetic (genotype, sex, race or ethnic background) and environmental (diet, disease, concurrent medication, other xenobiotic exposure) factors. The pathway and rate of a given compound's biotransformation is a function of each individual's unique phenotype with respect to the forms and amounts of drug-metabolizing enzymes expressed.

The **CYP enzymes** are quantitatively the most important of the phase I enzymes. These heme-containing proteins catalyze the metabolism of many lipophilic endogenous substances (i.e., steroids, fatty acids, fat-soluble vitamins, prostaglandins, leukotrienes, and thromboxanes) as well as xenobiotic compounds, including a multitude of drugs and environment toxins. CYP nomenclature is based on evolutionary considerations and uses the root symbol CYP for cytochrome P450. CYP enzymes that share at least 40% homology are grouped into families denoted by an Arabic number after the CYP root. Subfamilies, designated by a letter, appear to represent clusters of highly related genes. Members of the human CYP2 family, for example, have >67% amino acid sequence homology. Individual P450s in a subfamily are numbered sequentially (e.g., CYP3A4, CYP3A5). CYP enzymes that have been identified as being important in human drug metabolism are predominantly found in the CYP1, CYP2, and CYP3 gene families. Importantly, enzyme activity may be induced or inhibited by various agents (see Table 59-2).

For most CYP enzymes, genotype–phenotype relationships are influenced by development in that fetal expression is limited (with the exception of CYP3A7) and functional activity is acquired postnatally in isoform-specific patterns.

**Phase II enzymes** include arylamine N-acetyltransferases (NAT1, NAT2), glucuronosyltransferases (UGTs), epoxide hydrolase, glutathione S-transferases, sulfotransferases, and methyltransferases (catechol O-methyltransferase, thiorurine S-methyltransferase, several N-methyltransferases). Like the CYPs, UGTs, sulfotransferases, and glutathione S-transferases are gene families with multiple individual isoforms, each having its own preferred substrates, mode of regulation, and tissue-specific pattern of expression.

Clearance of some compounds appears to be greater in children relative to adults and the correlation between genotype and phenotype in neonatal life through adolescence may be overridden by these developmental phenomena.

**CYP2D6**

The CYP2D6 gene locus is highly polymorphic, with more than 100 allelic variants identified to date (http://www.cypalleles.ki.se/cyp2d6.htm; see Table 59-2). Individual alleles are designated by the gene name (CYP2D6) followed by an asterisk, and an Arabic number. By convention, CYP2D6*1 designates the fully functional wild-type allele. Allelic variants are the consequence of point mutations, single base-pair deletions or additions, gene rearrangements, or deletion of the entire gene, resulting in a reduction or complete loss of activity. Inheritance of 2 recessive loss-of-function alleles results in the **poor-metabolizer phenotype**, which is found in approximately 5-10% of white subjects and approximately 1-2% of Asian subjects. In white subjects, the *3, *4, *5, and *6 alleles are the most common loss-of-function alleles and account for approximately 98% of poor-metabolizer phenotypes. In contrast, CYP2D6 activity on a population basis tends to be lower in Asian and African-American populations because of a lower frequency of nonfunctional alleles (*3, *4, *5, and *6) and a relatively high frequency of population-selective alleles that are associated with decreased activity relative to the wild-type CYP2D6*1 allele. The CYP2D6*10 allele occurs as a frequency of approximately 50% in Asians, whereas CYP2D6*17 and CYP2D6*29 occur at relatively high frequencies in subjects of black African origin.

CYP2D6 is involved in the biotransformation of more than 40 therapeutic entities, including several β-receptor antagonists, antiarrhythmics, antidepressants, antipsychotics, and morphine derivatives (for an updated list, see http://static.medicine.iupui.edu/divisions/clinpharm/content/p450_Table_Oct_11_2009.pdf; see Table 59-2). CYP2D6 substrates commonly encountered in pediatrics include selective serotonin inhibitors (SSRIs; fluoxetine, paroxetine, sertraline), risperidone, atomoxetine, promethazine, tramadol, and codeine. Furthermore, nonprescription cold remedies such as dextromethorphan, diphenhydramine, and chlorpheniramine are also CYP2D6 substrates. An analysis of CYP2D6 ontogeny in vitro that utilized a relatively large number of samples revealed that CYP2D6 protein and activity remain relatively constant after 1 wk of age up to 18 yr. Similarly, results from an in vivo longitudinal phenotyping study involving more than 100 infants over the 1st year of life demonstrated considerable interindividual variability in CYP2D6 activity, but no relationship between CYP2D6 activity and postnatal age between 2 wk and 12 mo of age. Furthermore, a cross-sectional study involving 586 children reported that the distribution of CYP2D6 phenotypes in children was comparable to that observed in adults by at least 10 yr of age. Thus, both available in vitro and in vivo data, albeit based on phenotype data rather than information on drug clearance from pharmacokinetic studies, imply that genetic variation is more important than developmental factors as a determinant of CYP2D6 variability in children.

One consequence of CYP2D6 developmental pharmacogenetics may be the syndrome of irritability, tachypnea, tremors, jitteriness, increased muscle tone, and temperature instability in neonates born to mothers receiving SSRIs during pregnancy. Controversy currently exists as to whether these symptoms reflect a neonatal withdrawal (hyposerotonergic) state or represent manifestations of serotonin toxicity analogous to the hyposerotonergic state associated with the SSRI-induced serotonin syndrome in adults (see Chapter 106.1). Delayed expression of CYP2D6 (and CYP3A4) in the 1st few wk of life is consistent with a hyposerotonergic state caused by delayed clearance of paroxetine and fluoxetine (CYP2D6) or sertraline (CYP3A4) in neonates exposed to these compounds during pregnancy. Furthermore, decreases in plasma SSRI concentrations and resolution of symptoms would be expected with increasing postnatal age and maturation of these pathways. Given that treatment of a “withdrawal” reaction may include administration of an SSRI, there is considerable potential for increased toxicity in affected neonates. Resolution of the question whether symptoms are caused by withdrawal vs a hyposerotonergic state is essential for appropriate management of SSRI-induced neonatal adaptation syndromes. Until further data are available, it is prudent to consider newborns and infants younger than 28 days of age as CYP2D6 genotypic poor metabolizers.

In older children, drug accumulation and resultant concentration-dependent toxicities in CYP2D6 genotypic poor metabolizers should be anticipated in the same way that they are in adults because of the risk of significant morbidity and mortality. Although a fluoxetine-related death has been reported in a 9 yr old child with a CYP2D6 poor metabolizer genotype, experience with paroxetine indicates that the risk of drug accumulation may also occur, under certain conditions, in individuals at the opposite end of the activity spectrum. The pharmacokinetics of paroxetine and nefazodone, both CYP2D6 substrates, correlate with the CYP2D6 phenotype in children and adolescents...
7-17 yr of age. However, chronic dosing of paroxetine may lead to greater-than-anticipated drug accumulation in children classified as CYP2D6 extensive metabolizers. In depressed children and adolescents, as well as in adults, there is a disproportionate increase in peak concentrations and area under the serum concentration–time curves at higher dose levels. However, nonlinearity is more prominent in patients who are CYP2D6 extensive metabolizers, especially those with gene duplications and 3 or more functional alleles. The largest decreases in paroxetine clearance observed with ascending doses are seen in patients who have the greatest clearance at the initial dose level (10 mg/day) and are predicted to have the greatest CYP2D6 activity based on CYP2D6 genotype. This seemingly paradoxical effect is best explained in the context of data from in vitro studies. One proposed mechanism involves oxidation of paroxetine within the CYP2D6 active site to form a reactive intermediate that is associated with irreversible modification of the CYP2D6 protein in or near the active site. In theory, the greater the initial CYP2D6 activity, the greater the burden of reactive metabolite burden that is formed and thereby an increased loss of CYP2D6 catalytic activity. As a consequence, as the paroxetine dose is increased in patients with higher initial drug clearance, the risk of excessive drug accumulation increases disproportionately.

Theoretically, younger children may experience decreased efficacy or therapeutic failure with drugs such as codeine and tramadol that are dependent on functional CYP2D6 activity for conversion to the pharmacologically active species. CYP2D6 catalyzes the O-demethylation of inactive codeine to active morphine. Infants and children appear capable of converting codeine to morphine and achieving morphine: codeine ratios comparable to those of adults. However, in one study, morphine and its metabolites were not detected in 36% of children receiving codeine, making the level of analgesia from codeine unreliable in the studied pediatric population. Interestingly, in this study levels of morphine and its metabolites were not related to CYP2D6 phenotypes. Finally, ultrarapid CYP2D6 metabolism of codeine may result in opiate intoxication, including maternal ultrarapid metabolism of codeine, which can result in high serum and breast milk concentrations of morphine and may have adverse effects in the breastfed neonate.

**CYP2C9**

Although several clinically useful compounds are substrates for CYP2C9 (http://static.medicine.iupui.edu/divisions/clinpharm/content/p450_Table_Oct_11_2009.pdf; see Table 59-2), the effects of allelic variation are most profound for drugs with a narrow therapeutic index, such as phenytoin, warfarin, and tolbutamide. In vitro studies show a progressive increase in CYP2C9 expression from 1-2% of mature levels in the 1st trimester to approximately 30% at term. Considerable variability (approximately 35-fold) in expression is apparent over the 1st 5 mo of life, with approximately one-half of the samples studied exhibiting values equivalent to those observed in adults. One interpretation of these data is that there is broad interindividual variability in the rate at which CYP2C9 expression is acquired after birth, and in general, the onsets of CYP2C9 activity in vivo, as inferred from pharmacokinetic studies of phenytoin in newborns, is consistent with the in vitro results. The apparent half-life of phenytoin is prolonged (approximately 75 hr) in preterm infants, but decreases to approximately 20 hr in term newborns. By 2 wk of age, the half-life has further declined to 8 hr. Concentration-dependent (saturable) metabolism of phenytoin, reflecting the functional acquisition of CYP2C9 activity, does not appear until approximately 10 days of age. The maximal velocity of phenytoin metabolism is reported to decrease from an average of 14 mg/kg/day in infants to 8 mg/kg/day in adolescents, which may reflect changes in the ratio of liver mass to total body mass observed over this period of development, as has been observed for warfarin.

At least 56 allelic variants of CYP2C9 have been reported, but not all have been evaluated for their functional consequences. The CYP2C9*2 allele is associated with approximately 5.5-fold decreased intrinsic clearance for S-warfarin relative to the wild-type enzyme. Allelic variations resulting in amino acid changes within the enzyme active site, such as the CYP2C9*3, CYP2C9*4, and CYP2C9*5 alleles, are associated with activities that are approximately 5% of the wild-type protein. Approximately one-third of the white population carries a variant CYP2C9 allele (*2 and *3 alleles, most commonly), whereas the *2 and *3 alleles are virtually nonexistent in African-American, Chinese, Japanese, and Korean populations. In contrast, the *5 allele has been detected in African-Americans, but not in white subjects. The risk of bleeding complications in patients treated with warfarin and with concentration-dependent toxicity in patients treated with phenytoin is most pronounced for individuals with a CYP2C9*5/*3 genotype.

Compared to adults, the pharmacogenetics of warfarin dosing has not been studied as extensively in children. In adults, genetic variation in CYP2C9 and the warfarin target, VKORC1, as well as patient age, sex and weight, can account for 50-60% of the variation in warfarin dose requirements. A large fraction of the source of variation is still unknown, but it may be at least partially attributed to interactions with other drugs and foods. Studies in children demonstrate that the contribution of VKORC1 and CYP2C9 genotypes to variability in warfarin dose to achieve a stable international normalized ratio is quite variable, ranging from <5% to approximately 30%, and in each study the contribution of age, or a developmental variable that correlates with age (e.g., height or weight) accounts for the largest amount of variability. The factors contributing to differences between children and adults, and especially among the published pediatric studies, are not clear at this time.

**CYP2C19**

In vitro, CYP2C19 protein and catalytic activity can be detected at levels representing 12-15% of mature values by 8 wk of gestation and remain essentially unchanged throughout gestation and at birth. Over the 1st 5 mo of postnatal age, CYP2C19 activity increases linearly. Adult levels are achieved by 10 yr of age, although variability in expression is estimated to be approximately 21-fold between 5 mo and 10 yr of age. The major source of this variability is likely pharmacogenetic in nature. The CYP2C19 poor-metabolizer phenotype (also known as mefenonyl hydroxylase deficiency) is present in 3-5% of the white population and 20-25% of Asians. Although 25 variant alleles have been reported to date, the 2 most common variant alleles, CYP2C19*2 and CYP2C19*3, result from single base substitutions that introduce premature stop codons and, consequently, truncated polypeptide chains that possess no functional activity. Despite consistent increases in CYP2C19 activity observed in vitro over the 1st 5 mo of life, the results of an in vivo phenotyping study with omeprazole in Mexican children revealed a broad range of activity and implied that 17% of infants younger than 4 mo of age could be classified as poor metabolizers (no poor metabolizers were detected beyond that point). In contrast, 20% of children 3-9 mo old were classified as ultrarapid metabolizers compared with 6% of infants 1-3 mo of age. Similarly, a series of studies investigating pantoprazole pharmacokinetics in newborns, children and adolescents has revealed that the apparent oral clearance of pantoprazole is independent of CYP2C19 genotype in the 1st 2-3 mo after birth, but poor metabolizers can be distinguished from extensive metabolizers after 4-6 mo of age. The pharmacokinetic parameters of omeprazole are comparable to those observed in adults are achieved by 2 yr of age.

CYP2C19 also plays an important role in the metabolism of lansoprazole. In Japanese adults treated with lansoprazole, amoxicillin, and clarithromycin for Helicobacter pylori infection, the eradication rate for CYP2C19 poor metabolizers (97.8%) and heterozygous extensive metabolizers (1 functional CYP2C19 allele; 92.1%) was significantly greater than that observed in homozygous extensive metabolizers (72.7%). Of the 35 patients in whom initial treatment did not eradicate H. pylori, 34 had at least 1 functional CYP2C19 allele and eradication could be achieved with higher lansoprazole doses in almost all cases. Given that the frequency of the functional CYP2C19*1 allele is considerably greater in white subjects (approximately 0.84 [84%]) compared with Japanese subjects (approximately 0.55 [55%]), eradication failure can be expected to occur more frequently in whites. Because
proton pump inhibitors are widely used in children, pharmacogenetic as well as developmental considerations should guide pediatric dosing strategies.

**CYP3A4, CYP3A5, and CYP3A7**

The CYP3A subfamily consists of 4 members in humans (CYPs 3A4, 3A5, 3A7, and 3A43) and is quantitatively the most important group of CYP enzymes in terms of human hepatic drug biotransformation. These isozymes catalyze the oxidation of many different therapeutic entities, several of which are of potential importance to pediatric practice (for an updated list, see http://static.medline.com/pdfs/chlpharm/content/p450_Table_Oct_11_2009.pdf; see Table 59-2). CYP3A7 is the predominant CYP isoform in fetal liver and can be detected in embryonic liver as early as 50-60 days' gestation. CYP3A4, the major CYP3A isoform in adults, is essentially absent in fetal liver, but increases gradually throughout childhood. Over the 1st 6 mo of life, CYP3A7 expression exceeds that of CYP3A4, although its catalytic activity toward most CYP3A substrates is rather limited compared with that of CYP3A4. CYP3A4 is also abundantly expressed in intestine, where it contributes significantly to the first-pass metabolism of orally administered drugs which are substrates (i.e., midazolam). CYP3A5 is polymorphically expressed and is present in approximately 25% of adult liver samples studied in vitro.

Several methods have been proposed to measure CYP3A activity. Using these various phenotyping probes, CYP3A4 activity has been reported to vary widely (up to 50-fold) among individuals, but the population distributions of activity are essentially unimodal and evidence for polymorphic activity has been elusive. Although 24 allelic variants have been identified to date (http://www.cypalleles.ki.se/cyp3a4.htm), most occur relatively infrequently and do not appear to be of clinical importance. Of interest to pediatrics is the CYP3A4*1B allele present in the CYP3A4 promoter region. The clinical significance of this allelic variant appears limited with respect to drug biotransformation activity, despite being associated with 2-fold increased activity over the wild-type CYP3A4*1 allele in in vitro assays. Although there does not appear to be an association between the CYP3A4*1B allele and age of menarche, a significant relationship does exist between the number of CYP3A4*1B alleles and the age at onset of puberty, as defined by Tanner breast score. In one study, 90% of 9 yr old girls with a CYP3A4*1B/*1B genotype had a Tanner breast score of ≥2 compared with 56% of CYP3A4*1A/*1B heterozygotes and 40% of girls homozygous for the CYP3A4*1A allele. Because CYP3A4 plays an important role in testosterone catabolism, the authors of the latter study proposed that the estradiol: testosterone ratio may be shifted toward higher values in the presence of the CYP3A4*1B allele and trigger the hormonal cascade that accompanies puberty. Intestinal CYP3A4 activity is inhibited by grapefruit juice and may result in higher levels of the many drugs metabolized by this enzyme; very large quantities of grapefruit juice may also inhibit the hepatic CYP3A4.

The CYP3A4*22 allele has received attention due to its association with reduced clearance of statins in adults as well as immunosuppressants, such as cyclosporine and tacrolimus, in children and adults. Improved response to inhaled fluticasone has also been reported in children and adults. N-acetyltransferase activity, such as N-acetylation of cyclosporine and tacrolimus, in children and adults. Improved response to inhaled fluticasone has also been reported in children and adults.

Polymorphic CYP3A5 expression is largely the result of a SNP in intron 3 that creates a cryptic splice site and gives rise to messenger RNA splice variants that retain part of intron 3 with a premature stop codon. The truncated messenger RNA transcripts associated with this allele, CYP3A5*3, cannot be translated into a functional protein. Individuals with at least 1 wild-type CYP3A5*1 allele express functional CYP3A5 protein, whereas those homozygous for CYP3A5*3 (CYP3A5*3/*3) do not express appreciable amounts of functional protein. Approximately 60% of African-Americans show functional hepatic CYP3A5 activity compared with only 33% of European Americans. Clinically important consequences of CYP3A5 allelic variation have been reported in children. In pediatric heart transplant patients with a CYP3A5*1/*3 genotype, tacrolimus concentrations were approximately 50% of those observed in patients with CYP3A5*3/*3 genotypes, when corrected for dose, 3 mo, 6 mo, and 12 mo after transplant. Thus, larger doses of tacrolimus are required in patients with functional CYP3A5 protein to achieve comparable blood levels and to minimize the risk of rejection.

**Glucuronosyltransferases**

The UGT gene superfamily catalyzes the conjugation (with glucuronic acid) of several drugs used clinically in pediatrics, including morphine, acetaminophen, nonsteroidal anti-inflammatory drugs, and benzodiazepines. The effect of development on glucuronidation capacity has been well described and is illustrated by hyperbilirubinemia, gray baby syndrome (the cardiovascular collapse associated with high doses of chloramphenicol in newborns), and the 3.5-fold increase in morphine clearance observed in premature neonates at 24-39 wk postconceptual age. As with the CYPs, there are multiple UGT isoforms, and the acquisition of functional UGT activity appears to be isoform- and substrate-specific.

UGT1A1 is the major UGT gene product responsible for bilirubin glucuronidation, and more than 100 genetic alterations have been reported (Table 59-3), most of which are rare and are more properly considered mutations rather than gene polymorphisms (see Chapters 102 and 357.1). Inheritance of 2 defective alleles is associated with reduced bilirubin-conjugating activity and gives rise to clinical conditions, such as Crigler-Najjar syndrome and Gilbert syndrome. More frequently occurring polymorphisms involve a dinucleotide (TA) repeat in the atypical TATA box of the UGT1A1 promoter. The wild-type UGT1A1*1 allele has 6 repeats (TA6), and the TA7 (UGT1A1*33), TA8 (UGT1A1*28), and TA9 (UGT1A1*34) variants are all associated with reduced activity. UGT1A1*28, the most frequent variant, is a contributory factor to prolonged neonatal jaundice. This variant is also associated with impaired glucuronidation and thus toxicity of the active metabolite, SN-38, of the chemotherapeutic agent irinotecan. Allelic variations in UGT1A7 and UGT1A9 are also associated with irinotecan toxicity in adults with colorectal cancer.

The consequences of allelic variation in the UGT2B family are less certain. The predominant routes of morphine elimination include biotransformation to the pharmacologically active 6-glucuronide and the inactive 3-glucuronide. 6-Glucuronide formation is almost exclusively catalyzed by UGT2B7, whereas several UGTs in the UGT1A subfamily and UGT2B7 both contribute to 3-glucuronide formation. Increased 6-glucuronide: morphine ratios have been reported in individuals homozygous for the SNPs constituting the UGT2B7*2 allele. Although individuals genotyped as UGT2B7*2/*2 may produce higher than anticipated concentrations of pharmacologically active morphine and its metabolites, prospective pharmacogenetic studies addressing phenotype-genotype correlations and the consequences of morphine analgesia have had conflicting results.

**Arylamine N-Acetyltransferases**

One of the earliest discovered and most widely recognized genetic polymorphisms is the NAT2 polymorphism. Approximately 50% of whites and African-Americans in North America are phenotypically slow metabolizers, placing a substantial number of individuals at increased risk for the development of adverse drug effects, such as sulfasalazine-induced hemolysis, hydrazine or arylamine-induced peripheral neuropathy, procainamide- or isoniazid-induced systemic lupus erythematosus, and Stevens-Johnson syndrome or toxic epidermal necrolysis associated with sulfonamide administration. NAT2 function is inherited in an autosomal dominant fashion, with the inheritance of 2 “slow” alleles required for expression of the slow metabolizer phenotype. The relative proportion of rapid and slow metabolizers varies considerably with ethnic or geographic origin. The percentage of slow acetylators among Canadian Eskimos is 5%, but it approaches 90% in some Mediterranean populations.

In vivo, with the use of caffeine as a phenotyping probe, all infants 0-55 days of age appear to be phenotypically slow acetylators, whereas 50% and 62% of infants 122-224 and 225-342 days of age, respectively, can be characterized as fast acetylators. Several independent studies indicate that maturation of the NAT2 phenotype occurs during the 1st yr of life. Phenotype-genotype discordance is likely to be most

HLA, human leukocyte antigen; TPMT, thiopurine methyltransferase.

Thiopurine S-Methyltransferase
Thiopurine S-methyltransferase (TPMT) is a cytosolic enzyme that catalyses the S-methylation of aromatic and heterocyclic sulfur-containing compounds, such as 6-mercaptopurine (6MP), azathioprine, and 6-thioguanine, used in the treatment of acute lymphoblastic leukemia (ALL), inflammatory bowel disease, juvenile arthritis, and for the prevention of renal allograft rejection. To exert its cytotoxic effects, 6MP requires metabolism to thioguanine nucleotides by a multistep process that is initiated by hypoxanthine guanine phosphoribosyl transferase. TPMT prevents thioguanine nucleotide production by methylating 6MP (Fig. 59-4A). TPMT activity is usually measured in erythrocytes, with activity in erythrocytes reflecting which is found in other tissues, including liver and leukemic blasts. Although approximately 89% of whites and African-Americans have high TPMT activity and 11% have intermediate activity, 1 in 300 individuals inherit TPMT deficiency as an autosomal recessive trait (Fig. 59-4B). In newborn infants, peripheral blood TPMT activity is reported to be 50% greater than in race-matched adults and shows a distribution of activity that is consistent with the polymorphism characterized in adults. There are no data currently to indicate how long this higher activity is maintained, although TPMT activities were comparable to previously reported adult values in a population of Korean schoolchildren age 7-9 yr. In patients with intermediate or low activity, more drug is shunted toward production of cytotoxic thioguanine nucleotides. TPMT can also methylate 6-thioinosine S’-monophosphate to generate a methylated metabolite that is capable of inhibiting de novo purine synthesis (Fig. 59-4C). Three mutations have been identified in the TPMT gene (*2, *3A, *3C), which account for 98% of white subjects with low activity. These mutations encode proteins that undergo rapid protelysis resulting in low enzyme activity.

TPMT*3A is the most common mutant allele and is characterized by 2 nucleotide transition mutations, G460A and A719G, that lead to 2 amino acid substitutions, Ala154Thr and Tyr240Cys (see Fig. 59-4D). Although the *3A allele only has a frequency of 0.03% in the general population, it represents 55% of all mutant alleles. Either mutation alone results in loss of functional activity through the production of unstable proteins that are subject to accelerated proteolytic degradation. Less-frequent allelic variants involve SNPs that produce amino acid substitutions in the coding region and defective intron–exon splicing. A polymorphic locus has been identified in the promoter region of the TPMT gene involving 4-8 repeats of a specific nucleotide sequence in tandem. Although these repeats appear to modulate TPMT activity when expressed in vitro, their role in regulating activity in vivo has not been clearly established.

The relatively few patients with low to absent TPMT activity (0.3%) are at increased risk for severe myelosuppression if treated with routine doses of thiopurines; thus, they require a 10–15-fold reduction in dose to minimize this risk. Furthermore, if not dosed properly, patients may be at increased risk for relapse as a result of inadequate or absent treatment with thiopurines. Given the expanding use of 6MP and azathioprine in pediatrics to treat inflammatory bowel disease and juvenile arthritis and to prevent renal allograft rejection, TPMT pharmacogenetics is not a trivial matter.

Introduction of the TPMT phenotype or genotype determination into pediatric practice will lead to safer, more efficacious treatment in pediatric patient groups. Although the majority of research has been conducted in patients with acute lymphoblastic leukemia, the observation that patients classified as having intermediate TPMT activity are more likely to be intolerant of 6MP or azathioprine and likely will require more frequent dosage reductions in response to drug-induced myelosuppression is equally applicable to other pediatric patient groups (i.e., patients with Crohn disease) treated with this family of drugs.

PHARMACOGENETICS OF DRUG TRANSPORTERS
There are several major types of membrane transporters, including organic anion transporter (OAT), organic anion transporting polypeptides (OATPs), organic cation transporting proteins (OCTs), and the adenosine triphosphate–binding cassette (ABC) transporters, such as P-glycoprotein and the multidrug-resistant proteins (MRPs).
Membrane transporters are heavily involved in drug disposition and actively transport substrate drugs between organs and tissues. Drug transporters are expressed at numerous epithelial barriers, such as intestinal epithelial cells, hepatocytes, renal tubular cells, and at the blood–brain barrier (Fig. 59-5). Transporters often are also determinants of drug resistance, and many drugs work by affecting the function of transporters. As such, polymorphisms in the genes encoding these proteins may have a significant effect on the absorption, distribution, metabolism, and excretion as well as the pharmacodynamic effect of a wide variety of compounds.

The Adenosine Triphosphate–Binding Cassette Superfamily

The ABC transporters belong to the largest known transporter gene family and translocate a variety of substrates, including chemotherapy agents. ABC multidrug transporter expression is implicated in tumor cell resistance to anticancer therapy, altered disposition of chemotherapy drugs, and toxic side effects associated with chemotherapy. More recently, the genetic heterogeneity of a number of the ABC transporter genes has been described. Apart from having at least 1 adenosine triphosphate (ATP)-binding domain, these transporters are...
**DURING GROWTH AND DEVELOPMENT**

**CHANNELS, AND OTHER DRUG TARGETS**

**POLYMORPHISMS IN DRUG RECEPTORS, ION CHANNELS, AND OTHER DRUG TARGETS DURING GROWTH AND DEVELOPMENT**

**PHARMACOGENETICS OF DRUG RESPONSE: POLYMORPHISMS IN DRUG RECEPTORS, ION CHANNELS, AND OTHER DRUG TARGETS DURING GROWTH AND DEVELOPMENT**

Receptors are the targets for drugs and endogenous transmitters because of their inherent molecular recognition sites. Drugs and transmitters bind to the receptor to produce a pharmacologic effect. Variability in the receptor protein or the ion channel may determine the magnitude of the pharmacologic response. For example, polymorphisms of the β₂-adrenergic receptor gene (*ADRB2*) are associated with variable responses to bronchodilator drugs.

Drug responses are seldom monogenic events because multiple genes are involved in both drug binding to the pharmacologic target and the subsequent downstream signal transduction events that ultimately collectively manifest as a therapeutic effect. Although genotypes at a particular locus may show a statistically significant effect on the outcome of interest, they may account for only a relatively small amount of the overall population variability for that outcome. For example, a particular group of SNPs in the corticotropin-releasing hormone receptor 1 (*CRHR1*) gene is associated with a statistically...
Figure 59-6 Polygenic determinants of drug response. The potential effects of 2 genetic polymorphisms are illustrated. In each panel, there is a profile for subjects who have 2 wild-type alleles (WT/WT), those who are heterozygous for 1 wild-type and 1 variant (V) allele (WT/V), and those who have 2 variant alleles (V/V) for the depicted gene. The top panel illustrates a potential polymorphism involving a drug-metabolizing enzyme where variant alleles result in decreased drug metabolism and greater exposure (as shown by the increasing area under the concentration-time curve [AUC]). The second panel illustrates a potential polymorphism involving a drug receptor and depicts variant alleles which result in decreased receptor sensitivity. Note that for each receptor type, there are 3 possibilities for drug exposure. At the bottom is a table that shows the 9 resulting combinations of drug-metabolism and drug-receptor genotypes and the corresponding drug-response phenotypes calculated from data shown in the second panel. These phenotypes allow for calculation of a therapeutic index (i.e., efficacy:toxicity, in this example these range from 13 [65%:5%] to 0.1 [10%:80%]), which results in the ability to perform an individualized risk:benefit assessment. (Adapted from Evans WE, McLeod HL: Pharmacogenomics—drug disposition, drug targets, and side effects. N Engl J Med 348:538–549, 2003.)
significant improvement in forced expiratory volume in 1 sec, but accounts for only 6% of the overall variability in response to inhaled corticosteroids (see Chapter 144). A series of subsequent studies has determined that allelic variation in several genes in the steroid pathway contributes to overall response to this form of therapy.

The listing and classification of receptors is a major initiative of the International Union of Pharmacology. The list of receptors and voltage-gated ion channels is available on the International Union of Pharmacology website (http://www.guidetopharmacology.org/).

CURRENT AND FUTURE APPLICATIONS FOR PHARMACOGENETICS AND PHARMACOGENOMICS IN PEDIATRICS

Progress being made in the treatment of ALL provides an outstanding example of how the application of pharmacogenomic principles can improve pediatric drug therapy (see Chapter 495). Despite improved understanding of the genetic determinants of drug response, however, many complexities remain to be resolved. Patients with ALL who have 1 wild-type allele and intermediate TPMT activity tend to have a better response to 6MP therapy than patients with 2 wild-type alleles and full activity. Reduced TPMT activity also places patients at risk for irradiation-induced secondary brain tumors and etoposide-induced acute myeloid leukemias. Pharmacogenetic polymorphisms of several additional genes also have the potential to influence successful treatment of ALL. Multiple genetic and treatment-related factors interact to create patient subgroups with varying degrees of risk, and these represent an opportunity for pharmacogenomic approaches to identify subgroups of patients who will benefit from specific treatment regimens and those who will be at risk for short- and long-term toxicities (Fig. 59-6).

The 20% of patients with ALL who do not respond to chemotherapy represent an additional challenge for pharmacogenomic research. Gene expression (microarray) studies in ALL blasts are able to discriminate among phenotypic subtypes and identify some individuals who are at risk for treatment failure. An analysis of acute treatment-induced changes in the gene response of ALL blasts obtained 1 day after the initiation of 6MP and methotrexate as single agents or in combinations of high-dose or low-dose methotrexate and 6MP showed several important insights into the cellular response to these treatments. Changes in gene expression were treatment-specific and could accurately discriminate among the 4 treatments. ALL cells of different molecular subtypes shared common cellular responses to treatment, suggesting that it may be possible to personalize treatment strategies in ALL.

Chapter 59: Pediatric Pharmacogenetics, Pharmacogenomics, and Pharmacoproteomics

Bibliography

The clinical pharmacology of a given drug reflects a multifaceted set of properties that pertain to its disposition and action, and the response (e.g., adverse effects, therapeutic effects, and therapeutic outcome) to their administration/use. The 3 most important facets of the clinical pharmacology of a drug are its pharmacokinetics, pharmacodynamics, and the role of genetic variability as it may impact drug disposition or action (i.e., pharmacogenomics) (see Chapter 59).

Pharmacokinetics describes the movement of a drug throughout the body and the concentrations (or amounts) of a drug that reach a given body space and/or tissue and its residence time therein. Pharmacokinetics of a drug are conceptualized by considering those characteristics which collectively, are the determinants of the dose–concentration–effect relationship; namely, absorption, distribution, metabolism and excretion. Pharmacodynamics describes the relationship between drug dose or drug concentration and response. The response may be desirable (effectiveness) or untoward (toxicity). Although in clinical practice the response to drugs in different patient populations is often described by a standard dosing or concentration range, response is best conceptualized along a continuum where the relationship between dose and response(s) are not linear. Pharmacogenetics is the study of how variant forms of human genes contribute to interindividual variability in either drug disposition (e.g., variant alleles of gene controlling the expression of a drug transporter) and/or response (e.g., variant alleles altering the drug–receptor interaction). The finding that drug responses can be influenced by the patient’s genetic profile has offered great hope for realizing individualized pharmacotherapy when the relationship between genotype and phenotype (either disease and/or drug response) is predictive of drug response (see Chapter 59). In the developing child, it is apparent ontogeny that has the potential of modulating drug response through altering both pharmacokinetics and pharmacodynamics.

**GENERAL PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES**

Drug effect is produced only when an exposure (both amount and duration) occurs that is sufficient to produce a drug–receptor interaction capable of modulating the cellular milieu and inducing a biologic response. Thus, exposure–response relationships for a given drug represent an interface between pharmacokinetics and pharmacodynamics that can be simply conceptualized by consideration of 2 profiles: (1) plasma concentration vs effect (Fig. 60-1) and (2) plasma concentration vs time (Fig. 60-2).

The relationship between drug concentration and effect for most drugs is not linear (see Fig. 60-1). At a drug concentration of zero, the effect from the drug is generally zero or not perceptible (E0). Following drug administration and/or with dose escalation, the concentration increases as does the effect; first in an apparent linear fashion (at low drug concentrations) followed by a nonlinear increase in effect to an asymptotic point in the relationship where a maximal effect (Emax) is attained that does not perceptibly change with further increases in

*Figure 60-1 Plasma concentration vs effect curve. The percent effect is measured as a function of increasing drug concentration in the plasma. The dose at which no effect is seen in the population is E0. The dose of a drug required to produce a specified effect in 50% of the population is abbreviated as EC50. The concentration associated with the maximal effect that can be produced by a drug is abbreviated as Emax. (From Abdel-Rahman SM, Kearns GL. The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In Feigin RD, Cherry JD, Demmler-Harrison GJ, Kaplan SL, editors, Textbook of pediatric infectious disease, ed 6, Philadelphia, 2009, WB Saunders, pp. 3156–3178, reproduced with permission.)*
Figure 60-2 Semilogarithmic plot of the plasma concentration vs time curve for a hypothetical drug following extravascular administration. The area under the plasma level-time curve (AUC) is a concentration and time-dependent measure of systemic drug exposure. After administration, the drug is absorbed and reaches the maximal concentration (C_{max}) at its peak time (T_{max}). Following completion of drug absorption and distribution, plasma drug concentrations decline in an apparent monoexponential fashion whereby the slope of the apparent elimination phase represents the apparent elimination rate constant (ke). (From Abdel-Rahman SM, Kearns GL. The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In Feigin RD, Cherry JD, Demmler-Harrison GJ, Kaplan SL, editors. Textbook of pediatric infectious disease, ed 6, Philadelphia, 2009, WB Saunders, pp. 3156–3178, reproduced with permission.)

Drugs that may be in a given drug class. In practice, Emax can be derived from visual interpolation of the concentration–effect profile or either from mathematical curve fitting of the relationship.

Because it is rarely possible to measure drug concentrations at or near the receptor, it is necessary to utilize a surrogate measurement to assess exposure–response relationships. In most instances, this surrogate is represented by the plasma drug concentration vs time curve. For drugs whose pharmacokinetic properties are best described by 1st-order (as opposed to zero-order or mixed-order) processes, a semilogarithmic plot of plasma drug concentration vs time data for an agent given by an extravascular route of administration (e.g., intramuscular, subcutaneous, intracisternal, peroral, transmucosal, transdermal, rectal) produces a pattern similar to that illustrated by Figure 60-2. The ascending portion of this curve represents a time during which the liberation of a drug from its formulation, dissolution of the drug in a biologic fluid (e.g., gastric or intestinal fluid, interstitial fluid; a prerequisite for absorption) and absorption of a drug are rate-limiting relative to its elimination. After the time (T_{max}) where maximal plasma concentrations (C_{max}) are observed, the plasma concentration decreases as metabolism and elimination become rate limiting; the terminal portion of this segment of the plasma concentration vs time curve being representative of drug elimination from the body. Finally, the area under the plasma concentration vs time curve (AUC), a concentration- and time-dependent parameter reflective of the degree of systemic exposure from a given drug dose, can be determined by integrating the plasma concentration data over time. By being able to characterize the pharmacokinetics of a specific drug, the clinician can use the data to individualize dosing regimens for patients who by virtue of development and/or disease, must have adjustments to either the dose and/or dosing interval so as to enable the production of the degree of systemic exposure associated with desired pharmacologic effects. For drugs where a therapeutic plasma concentration range and/or “target” systemic exposure (i.e., AUC) is known, a priori knowledge of pharmacokinetic parameters for a given population or patient within a population can facilitate the selection of a drug dosing regimen. When linked with information regarding the pharmacodynamic behavior of a drug and the status of the patient (e.g., age, organ function, disease state, concomitant medications), the application of pharmacokinetics affords the practitioner the ability to exercise some real degree of adaptive control over therapeutic decision making by enabling the selection of a drug and dosing regimen that has the greatest likelihood of producing both efficacy and safety.

THE IMPACT OF ONTOGENY ON DRUG DISPOSITION

Development represents a continuum of biologic events that enable adaptation, somatic growth, neurobehavioral maturation and eventually reproduction. The impact of development on the pharmacokinetics of a given drug is determined, to a great degree, by age-related changes in body composition and the acquisition of function in organs and organ systems, which are important in determining drug metabolism and excretion. Even though it is often convenient to classify pediatric patients on the basis of postnatal age for the provision of drug therapy (e.g., neonate 0–1 mo of age; infant 1–24 mo of age; children 2–12 yr of age; and adolescents 12–18 yr of age), it is important to recognize that the changes in physiology are not linearly related to age and may not correspond to these age-defined breakpoints. In fact, the most dramatic changes in drug disposition occur during the 1st 18 mo of life where the acquisition of organ function is most dynamic. Additionally, it is important to note that the pharmacokinetics of a given drug may be altered in pediatric patients consequent to intrinsic (e.g., gender, genotype, ethnicity, inherited diseases) or extrinsic (e.g., acquired disease states, xenobiotic exposure, diet, variability in therapeutic adherence) factors that may occur during the 1st 2 decades of life.

During development, certain stages of life profoundly influence drug response and disposition. Dramatic pharmacokinetic, pharmacodynamic, and psychosocial changes occur as preterm infants mature toward term, as infants mature through the 1st 5 years of life, and as children reach puberty and adolescence (Fig. 60-3). It is most useful to conceptualize the impact of ontogeny on drug disposition by considering its specific facets, namely, drug absorption, distribution, metabolism, and excretion, as well as ontogeny’s impact on drug action (pharmacodynamics).

Drug Absorption

Absorption usually occurs via passive diffusion, but active transport or facilitated diffusion also may be necessary for drug entry into cells. Several physiologic factors affect this process, 1 or more of which may be altered in the face of certain disease states (e.g., inflammatory bowel disease, diarrhea) and, consequently, produce changes in drug bioavailability. The rate and extent of absorption can be significantly affected as a consequence of a child’s normal growth and development.

Peroral Absorption

The most important factors that influence drug absorption from the gastrointestinal tract are related to the physiology of the stomach, intestine, and biliary tract (see Fig. 60-3C and Table 60-1). The rate and extent of peroral absorption of drugs depends primarily on the pH-dependent passive diffusion and motility of the stomach and intestinal tract as both of these factors will influence transit time of the drug. Gastric pH changes significantly throughout development with the highest (alkaline) values occurring during the neonatal period. In the fully mature neonate, the gastric pH ranges from 6–8 at birth and drops to 2–3 within a few hours of birth. However, after the 1st 24 hr of life, the gastric pH drifts upward because of the immaturity of the parietal cells. As the parietal cells mature, the gastric acid secretory capacity increases (pH decreases) over the 1st few months of life to reach consistent adult levels by 3–7 yr of age. As a result, the peroral bioavailability of acid-labile drugs, such as penicillin or ampicillin, is increased. In contrast, the absorption of weak organic acids (e.g., phenobarbital and phenytoin) is relatively decreased, a condition which may necessitate the administration of larger doses in the very young to achieve therapeutic plasma levels.
changes in gastrointestinal motility. In older infants and young children, more rapid rates of intestinal drug transit can reduce the bioavailability for some drugs (e.g., phenytoin) and/or drug formulations (e.g., sustained-release) by reducing their residency time at the absorption surfaces in the small intestine.

Lastly, neonates, particularly premature neonates, have a reduced bile acid pool and biliary function resulting in a decreased ability to solubilize and absorb lipophilic drugs. Even though biliary function

Gastric emptying time is prolonged throughout infancy and childhood consequent to reduced motility which may retard drug passage into the intestine where the majority of absorption takes place. Gastric emptying rates reach or exceed adult values by 6-8 mo of life. As such, intestinal motility is important for the rate of drug absorption and, like other factors, is dependent on the age of the child. Consequently, the rate of absorption of drugs with limited water solubility (e.g., phenytoin, carbamazepine) can be dramatically altered consequent to

Figure 60-3 Developmental changes in physiologic factors that influence drug disposition in infants, children, and adolescents. Physiologic changes in multiple organ systems during development are responsible for age-related differences in drug disposition. A, As this graph shows, the activity of many cytochrome P450 (CYP) isoforms and a single glucuronosyltransferase (UGT) isoform is markedly diminished during the 1st 2 mo of life. In addition, the acquisition of adult activity over time is enzyme- and isoform-specific. B, This chart shows age-dependent changes in body composition that influence the apparent volume of distribution of drugs. Infants in the 1st 6 mo of life have markedly expanded total-body water and extracellular water, expressed as a percentage of total-body weight, as compared with older infants and adults. C, This graph summarizes the age-dependent changes in both the structure and function of the gastrointestinal tract. As with hepatic drug-metabolizing enzymes (A), the activity of CYP1A1 in the intestine is low during early life. D, This chart shows the effect of postnatal development on the processes of active tubular secretion—represented by the clearance of paraaminohippuric acid and the glomerular filtration rate, both of which approximate adult activity by 6-12 mo of age. E, This graph shows age dependence in the thickness, extent of perfusion, and extent of hydration of the skin and the relative size of the skin-surface area (reflected by the ratio of body surface area to body weight). Although skin thickness is similar in infants and adults, the extent of perfusion and hydration diminishes from infancy to adulthood. (From Kearns GL, Abdel-Rahman SM, Alander SW, et al, Developmental pharmacology—drug disposition, action, therapy in infants and children. N Engl J Med 349:1157–1167, 2003. Direction of alteration given relative to expected normal adult pattern.

Develops in the 1st few months of life, it may be difficult for the neonate and young infant to absorb fat-soluble vitamins as low concentrations of bile acids are necessary for their absorption.

Extravascular Drug Absorption

With a bioavailability of 100%, intravenous drug administration is assumed to be the most dependable and accurate route for drug delivery. Absorption of drugs from tissues and organs (e.g., intramuscular, transdermal, and rectal) can also be affected by development (Table 60-2). Intramuscular blood flow changes with age, which can result in variable and unpredictable absorption. Reduced muscular blood flow in the 1st few days of life, the relative inefficiency of muscular contractions (useful in dispersing an IM drug dose), and an increased percentage of water per unit of muscle mass may delay the rate and/or extent of drugs given intramuscularly to the neonate. Muscular blood flow increases into infancy and, consequently, the bioavailability of drugs given by the IM route is comparable to that seen in children and adolescents.

In contrast, mucosal permeability (rectal and buccal) in the neonate is increased and thus, may result in enhanced absorption by this route. Transdermal drug absorption in the neonate and very young infant is increased as the result of a more hydrated stratum corneum (see Fig. 60-3C). In addition, the ratio of body surface area to body weight is greater in infants and children compared to adults. Collectively, these developmental differences may predispose the child to increased exposure and risk for toxicity for drugs/chemicals placed on the skin (e.g., silver sulfadiazine, topical corticosteroids, benzocaine, diphenhydramine) with higher likelihood of occurrence during the 1st 12 mo of life.

Normal developmental differences in drug absorption from most all extravascular routes of administration can influence the dose-plasma concentration relationship in a manner sufficient to alter pharmacodynamics. It should be recognized that the presence of disease states which influence a physiologic barrier for drug absorption and/or the time that a drug spends at a given site of absorption can further influence drug bioavailability and effect.

Drug Distribution

Drug distribution is influenced by a variety of drug-specific physiochemical factors (e.g., molecular size and weight, apparent partition coefficient, pKa), the presence of drug transporters, blood/tissue protein binding, blood and tissue pH1 and perfusion. However, age-related changes to drug distribution are primarily related to developmental changes in body composition and the quantity of plasma proteins capable of drug binding. Age-dependent changes in the relative sizes of body water (total body water [TBW], extracellular water) and fat compartments may alter the apparent volume of distribution (VD) for a given drug. The absolute amounts and distribution of body water and fat depend on a child's age and nutritional status. As well, certain disease states (e.g., ascites, dehydration, burn injuries, disruption of the integument involving large surface area) can influence body water compartment sizes and thereby, further impact the VD for certain drugs.

Newborns have a much higher proportion of body mass in the form of water (~75% TBW) than older infants and children (see Fig. 60-3B). As well, the percent of extracellular water changes (decreases) from the newborn stage (approximately 45%) into adulthood (approximately 20–30%). In fact, the increase of TBW in the neonate is attributable to extracellular water. The reduction in TBW is rapid in the 1st year of life with adult values (approximately 55%) achieved by approximately 12 yr of age. In contrast, the percentage of intracellular water as a function of body mass remains stable from the 1st months of life through adulthood. The impact of developmental changes in body water spaces are exemplified by drugs such as the aminoglycoside antibiotics; compounds that distribute predominantly throughout the extracellular fluid space and have a higher VD (0.4-0.7 L/kg) in neonates and infants as compared to adults (0.2-0.3 L/kg).

Body fat percentage and composition increase during normal development. The body fat percentage in a neonate is approximately 16% (57% water and 35% lipid). Despite the relatively low body fat content in the neonate, it is important to note that the lipid content in the developing central nervous system (CNS) is high, which has implications for the distribution of lipophilic drugs and their CNS effects (e.g., propranolol) during this time period. The body fat percentage tends to increase up to approximately 10 yr of age and then changes composition with respect to puberty and sex to approach adult body fat composition (26% water and 71% lipid). In addition, a sex difference exists as the child ages into adolescence. The total body fat in males is reduced by 50% between 10 and 20 yr of life as compared to females in whom the reduction is approximately 25%.

Albumin, total proteins, and total globulins (e.g., α1-acid glycoprotein) are the most important circulating proteins responsible for drug binding in plasma. The absolute concentration of these proteins is influenced by age, nutrition, and disease (Table 60-3). The concentrations of most all circulating plasma proteins are reduced in the neonate and young infant (approximately 80% of adult) and reach adult values by 1 year of age. A similar pattern of maturation is observed with α1-acid glycoprotein (an acute-phase reactant capable of binding basic drugs) where neonatal plasma concentrations are approximately 3 times lower than in maternal plasma and attain adult values by approximately 1 year of age.

The extent of drug binding to proteins in the plasma may influence distribution characteristics. Only free, unbound drug can be distributed from the vascular space into other body fluids and, ultimately, to tissues where drug–receptor interaction occurs. Drug protein binding depends on a number of age-related variables, which can include the absolute amount of proteins and their available binding sites; the conformational structure of the binding protein (e.g., reduced binding of

Acidic drugs to glycated albumin in patients with poorly controlled diabetes mellitus; the affinity constant of the drug for the protein; the influence of pathophysiologic conditions that either reduce circulating protein concentrations (e.g., ascites, major burn injury, chronic malnutrition, hepatic failure) or alter their structure (e.g., diabetes, uremia); and the presence of either endogenous or exogenous substances, which may compete for protein binding.

Developments associated with changes in drug binding can occur as a consequence of altered protein concentrations and/or binding affinity. For example, circulating fetal albumin in the neonate has significantly reduced binding affinity for acid drugs such as phenytoin, which is extensively (94-98%) bound to albumin in adults as compared to 80–85% in the neonate. The resultant 6-8-fold difference in the free fraction can result in CNS adverse effects in the neonate when total plasma phenytoin concentrations are within the generally accepted “therapeutic range” (10-20 mg/L). The importance of reduced drug-binding capacity of albumin in the neonate is exemplified by interactions between endogenous ligands (e.g., bilirubin, free fatty acids) and drugs with greater binding affinity (e.g., the ability of sulfonamides to produce kernicterus).

Drug transporters, such as P-glycoprotein, MDR1, and MDR2 (multidrug resistance 1 or 2), can influence drug distribution. These drug transporters can markedly influence the extent to which drugs cross membranes in the body and whether drugs can penetrate or are secreted from the target sites (inside cancer cells or microorganisms, or crossing the blood–brain barrier). Thus, drug resistance to cancer chemotherapy, antibiotics, or epilepsy may be conferred by these drug transport proteins and their effect on drug distribution. While there are limited data on the ontogeny of drug transport proteins, available information demonstrates their presence as early as 22 wk gestation and low levels in the neonatal period which appear to rapidly increase to adult values by 1-2 yr of age.

Drug Metabolism

Metabolism reflects the biotransformation of an endogenous or exogenous molecule by 1 or more enzymes to moieties that are more hydrophilic and thus, can be more easily eliminated by excretion, secretion, or exhalation. Although metabolism of a drug generally reduces its ability to produce a pharmacologic action, it can result in metabolites that have significant potency, thereby contributing to the overall pharmacodynamic profile of a drug (e.g., biotransformation of the tricyclic antidepressant amitriptyline to nortriptiline; cefotaxime to desacetylcefotaxime; theophylline to caffeine) or in some instances, can produce significant toxicity (e.g., biotransformation of codeine to morphine). In the case of prodrugs (e.g., zidovudine, enalapril, fosphenytoin) or some drug salts/esters (e.g., cefuroxime axetil, clindamycin phosphate), biotransformation is required to produce a pharmacologically active moiety. Finally, for some drugs, cellular injury and associated adverse reactions are the result of drug metabolism (e.g., acetaminophen hepatotoxicity, Stevens-Johnson syndrome associated with sulfamethoxazole).

The primary organ responsible for drug metabolism is the liver, although the kidney, small intestine, lung, adrenals, blood (phosphatases, esterases) and skin can also biotransform certain compounds. Drug metabolism occurs primarily in the endoplasmic reticula of cells via 2 general classes of enzymatic processes: phase I, or nonsynthetic, and phase II, or synthetic, reactions. Phase I reactions include oxidation, reduction, hydrolysis, and hydroxylation reactions, whereas phase II reactions primarily involve conjugation with an endogenous ligand (e.g., glycine, glucuronide, glutathione or sulfate). As illustrated by Figure 60-3A, many drug metabolizing enzymes demonstrate an ontogenetic profile with generally low activity present at birth and maturation over a period of months to years (Table 60-4).

Even though there are many enzymes that are capable of catalyzing the biotransformation of drugs and xenobiotics, the quantitatively most important are represented by the cytochromes P450 (CYPs), a supergene family with at least 16 primary enzymes. The specific CYP isoforms responsible for the majority of human drug metabolism are represented by CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. These enzymes represent the products of genes that in some instances, are polymorphically expressed with allelic variants producing enzymes generally resulting in either no or reduced catalytic activity (a notable exception being the *17 allele of CYP2C19 which conveys increased activity) (see Chapter 59). At birth, the concentration of drug-oxidizing enzymes in fetal liver (corrected for liver weight) appears similar to that in adult liver. However, the activity of these oxidizing enzymes is reduced, which results in slow clearance (and prolonged elimination) of many drugs that are substrates for them (e.g., phenytoin, caffeine, diazepam, and many others). Postnatally, the hepatic CYPs appear to mature at different rates. Within hours after birth, CYP2E1 activity increases rapidly with CYP2D6 being detectable soon thereafter. CYP2C (CYP2C9 and CYP2C19) and CYP3A4 are present within the 1st mo of life, and a few months later, CYP1A2. CYP3A4 activity in young infants may exceed that observed in adults as reflected by the clearance of drugs that are substrates for this enzyme (e.g., cyclosporine, tacrolimus).

Compared to phase I drug-metabolizing enzymes, the impact of development on the activity of phase II enzymes (acetylation, glucuronidation, sulfation) is not characterized as well. Generally speaking, phase II enzyme activity is decreased in the newborn and increases into childhood. For example, conjugation of compounds metabolized by isozymes of glucuronosyltransferase (UGT; e.g., morphine, bilirubin, and chloramphenicol) is reduced at birth but can exceed adult values by 3-4 yr of age. Also, the ontogeny of UGT expression is isozyme specific. Newborns and infants primarily metabolize the commonly used analgesic acetaminophen by sulfate conjugation whereas the UGT isozymes responsible for its glucuronidation (UGT1A1 and UGT1A9) have markedly reduced activity. As children age, the
Renal Drug Elimination

The kidney is the primary organ responsible for the excretion of drugs and their metabolites. The development of renal function begins during early fetal development and is complete by early childhood (see Fig. 60-3D, Table 60-5). Total renal drug clearance (CLrenal) can be conceptualized by considering the following equation:

\[
CL_{\text{renal}} = (\text{GFR} + \text{ATS}) - \text{ATR}
\]

where glomerular filtration rate (GFR), active tubular secretion (ATS), and active tubular reabsorption (ATR) of drugs can contribute to overall clearance. As is true for hepatic drug metabolism, only free (unbound) drug and/or metabolite can be filtered by a normal glomerulus and/or either secreted or reabsorbed via a renal tubular transport proteins.

Renal clearance is limited in the newborn by both anatomical and functional immaturity of the nephron unit. In both the term and preterm neonate, GFR averages 2-4 mL/min/1.73 m² at birth. During the 1st few days of life, a drop in renal vascular resistance occurs which results in a net increase in renal blood flow and a re-distribution of intrarenal blood flow from a predominantly medullary to a cortical distribution. All of these changes are associated with a commensurate increase in GFR. In term neonates, GFR increases rapidly over the 1st few months of life and approaches adult values by 10-12 mo of life (see Fig. 60-3D). The rate of GFR acquisition is blunted in preterm neonates consequent to continued nephrogenesis, which occurs in the early postnatal period. In young children between 2 and 5 yr of age, GFR may exceed adult values, especially during periods of increased metabolic demand (e.g., during a fever).

In addition, there is a relative glomerular/tubular imbalance because of a more advanced maturation of glomerular function. Such an imbalance may persist up to 6 mo of age and may account for the observed decrease in the ATS of drugs commonly used in neonates and young infants (e.g., β-lactam antibiotics). Finally, there is some evidence that ATR is reduced in neonates and that it appears to mature at a slower rate than the GFR.

Altered renal drug clearance in the newborn and infants result in the different dosing recommendations commonly seen in pediatrics. The aminoglycoside antibiotic gentamicin provides an illustrative example. In adolescents and young adults with normal values for GFR (85-130 mL/min/1.73 m²), the recommended dosing interval for the drug is 8 hr. In young children who may have a GFR >130 mL/min/1.73 m², a gentamicin dosing interval of every 6 hr may be necessary in selected patients who have serious infections that require maintaining steady-state peak and trough plasma concentrations near the upper boundary of the recommended therapeutic range. In contrast, to maintain “therapeutic” gentamicin plasma concentrations in neonates during the 1st few weeks of life, a dosing interval of 18-24 hr is required.

The impact of developmental differences in GFR on the elimination characteristics of a given drug can be assessed by estimating the apparent elimination rate constant (Kel) for a drug by using the following equation:

\[
\text{Kel (in reduced renal function)} = \frac{\text{Kel}_{\text{normal}} \cdot (\text{GFR}_{\text{observed}} / \text{GFR}_{\text{normal}} - 1) \cdot \text{Fel}}{1 + \text{Fel}}
\]

where the \(\text{Fel}\) represents the fraction of the drug excreted unchanged in an adult with normal renal function, \(\text{GFR}_{\text{observed}}\) is the value calculated (from creatinine clearance or an age-appropriate estimation equation) for the patient (in mL/min/1.73 m²), \(\text{GFR}_{\text{normal}}\) is the average value considered for a healthy adult (i.e., 120 mL/min/1.73 m²) and \(\text{Kel}_{\text{normal}}\) is estimated from the average elimination \(T_\text{1/2}\) (terminal half-life) for a drug taken from the medical literature using the following equation:

\[
\text{Kel}_{\text{normal}} [\text{hr}^{-1}] = 0.693 / T_{1/2}\text{normal} [\text{hr}]
\]
Likewise, the elimination $T_e$ for a drug in patients with reduced renal function can be estimated as follows:

$$T_e \text{ (in reduced renal function)} = 0.693/Ke \text{ (in reduced function)}$$

An estimate of the drug elimination $T_e$ in patients with reduced renal function with knowledge of the desired interdose excursion in steady-state plasma concentrations can provide an ability to determine the desired drug dosing interval.

**Impact of Ontogeny on Pharmacodynamics**

Although, it is generally accepted that developmental differences in drug action exist, there is little evidence of true age-related pharmacodynamic variation among children of differing age groups and adults. Drug action is typically mediated by interaction of a small molecule with 1 or more receptors, which may be located either on or in a cell. Drug effect is mediated at the receptor by 4 main biochemical mechanisms involved in cell signaling. Binding of the receptors on the cell surface or within the cell activate downstream pathways that mediate a specific cellular action. Some receptors act as enzymes whereby, upon ligand binding, the enzyme phosphorylates downstream effector proteins, thereby activating or inhibiting a cellular signal. Guanosine triphosphate–binding regulatory protein, also known as G-protein–coupled receptors, are known targets for many drugs. Upon ligand binding, guanosine triphosphate binds to and activates the G-protein, in turn allowing it to activate second messenger regulatory proteins in the cell, again mediating cellular signaling. Other receptors mediate their actions through ion channels whereby, upon ligand binding, the cell’s membrane potential or ionic composition is altered allowing cellular activation or inhibition. Lastly, some receptors act as transcription factors that, when bound by a ligand, transcription of specific genes within the cell are activated. Drug action is concentration dependent with onset and offset generally associated with appearance and disappearance, respectively, of the drug at the receptor(s) in an amount that is sufficient to initiate the cascade of biologic effects that terminate in drug action (see Fig. 60-1). The minimum effective concentration of a drug is that observed with the immediate onset of effect, whereas the duration of action is predicated upon the maintenance of drug concentrations at the receptor within a range that is associated with the desirable pharmacologic action(s). Receptor binding by a drug may have varying consequences. Drugs that are agonists bind to and activate the receptor, directly or indirectly achieving the desired effect. An agonist binding to a receptor results in the same biologic effect as binding of the endogenous ligand. Partial agonists bind to a receptor in activation of the receptor but maximal effect is not achieved even in the presence of receptor saturation. Antagonists bind to a receptor preventing binding of other molecules thereby preventing activation of the receptor.

Age-related pharmacokinetic variation resulting in altered drug disposition may result in less or more drug being available at the receptor(s) consequent to whether drug clearance is decreased or increased relative to values in adults. The resultant alteration in the dose–concentration profile may result in an attenuated (ineffective) or exaggerated (toxicity) response in children, which is especially relevant for drugs with a narrow therapeutic index (Fig. 60-4). Thus, in some circumstances, apparent developmental differences in drug response/ effect may be simply explained on pharmacokinetic basis.

There is evidence supporting developmental differences in receptor number, density, distribution, function, and ligand affinity for some drugs. As there are limited data from humans, much of what is known has been derived from animal studies. In the CNS, unique developmental aspects of drug–receptor interaction affect therapeutic efficacy of both analgesic and sedative drugs in neonates. For example, the number of γ-aminobutyric acid receptors, which mediates inhibitory signal transduction in the CNS, is reduced in newborns compared to adults. Functional differences have also been observed between neonatal and adult brain upon γ-aminobutyric acid receptor activation. These changes may explain observed differences in dosing of drugs such as midazolam in infants, and in part may explain seizures experienced by infants upon benzodiazepine exposure. Another example in the CNS is illustrated by the μ-opioid receptor whereby receptor number is reduced in newborns and receptor distribution also differs between newborns and adults.

For the clinician, the consideration of age-dependent differences in pharmacodynamics is particularly relevant when they are associated with adverse drug reactions (e.g., higher incidence of valproic acid-associated hepatotoxicity in young infants; greater frequency of paradoxical CNS reactions to diphenhydramine in infants; weight gain associated with use of atypical antipsychotic drugs in adolescents) or when drugs have a narrow therapeutic index. This latter situation is exemplified by the immunomodulatory agent cyclosporine and the anticoagulant warfarin. In children younger than 1 yr old, the mean concentration of cyclosporine required to inhibit monocyte proliferation and the expression of the inflammatory cytokine interleukin-2 is less than required in older children. The age-associated pharmacodynamics of warfarin observed in children with congenital heart disease is, to a great degree, associated with developmental differences in serum concentrations of vitamin-K dependent coagulation factors (II, VII, IX, X) between children and adults. Developmental differences in drug action have also been observed between prepubertal children and adults with regard to warfarin action. Prepubertal children compared to adults exhibit a more profound response, demonstrated by lower protein C concentration, prothrombin fragments 1 and 2, and greater rise in international normalized ratio, to comparable doses of warfarin. Thus, when age-dependent pharmacodynamics of a given drug are evident, the use of simple allometric approaches for “scaling” the pediatric dose from the usual adult dose may not produce the desired pharmacologic effects.

**Surrogate End Points**

The assessment of pharmacodynamics in human infants and children has been hampered historically by a relative inability to use invasive methods for the direct assessment of drug effect. As a result, surrogate end points and biomarkers have been explored and, in some cases, have been successfully used to evaluate the impact of ontogeny on pharmacodynamics.

Biomarkers and surrogate end points (markers) are ideally simple, reliable, inexpensive, and easily obtainable measures of a biologic response or disease phenotype that can be used to facilitate either clinical research or patient care. Biomarkers have been defined by the U.S. National Institutes of Health as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.” A surrogative end point is defined “as a biomarker that is intended to substitute for a specific clinical end point. A surrogate end point is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or...
other scientific evidence.” Reliable surrogate end points predict a specific physiologic event(s) (e.g., intraesophageal pH to assess gastroesophageal reflux), which may be utilized diagnostically, prognostically, or in predicting a specific drug response (therapeutic, subtherapeutic, or adverse) or potentially, the impact of ontogeny on pharmacodynamics. Specific examples of surrogate end points used in pediatric pharmacology include measurement of esophageal pH to assess the action of prokinetic or acid-modifying drugs, use of gastric scintigraphy and stable isotope-labeled compounds (e.g., 13C-acetate, 13C-octanoic acid) to assess gastric emptying rate, and pulmonary function tests (e.g., forced expiratory volume at 1 sec) to evaluate the effect(s) of drugs on pulmonary function in patients with conditions such as asthma and cystic fibrosis. Examples of biomarkers that have been used in pediatric studies to assess drug disposition or effect include hemoglobin A1c, plasma concentration (to assess efficacy of peroral hypoglycemic agents); urinary leukotriene concentrations (to assess effects of nonsteroidal antiinflammatory drugs); minimal inhibitory and minimal bactericidal concentrations of drugs to selected antiinfective agents; and the use of selective genotyping tests (e.g., projection of therapeutic warfarin dose requirement by use of CYP2C9 [gene controlling expression of the enzyme primarily responsible for warfarin metabolism] and VKORC1 [gene controlling expression of enzyme primarily involved in regulating warfarin effects on vitamin K dependent clotting factors] genotyping.

**Additional Considerations in Pediatric Therapeutics**

The use of adult-dose modification for pediatric dose prediction is based on the association between body size/composition and the physiologic determinants of drug disposition across the spectrum of age. Although these approaches may have some potential clinical utility in children older than 8 yr of age and in adolescents whose organ function and body composition approximates that of young adults, their utility is severely limited in neonates, infants, and children younger than 2 yr of age in whom ontogeny produces dramatic differences in drug disposition. This is especially problematic for therapeutic drugs whose doses cannot be easily individualized using patient-specific pharmacokinetic data obtained from therapeutic drug monitoring.

More than 20 different approaches for initial selection of a drug dose for pediatric patients have been described. The majority of these utilize either total body weight (BW) or body surface area (BSA) as surrogates, which reflect the developmental changes of either body composition or organ function that collectively are the major determinants of drug disposition. Dose selection based on BW or BSA will generally produce similar relationships between drug dose and resultant plasma concentration, except for those drugs whose apparent VD corresponds to the extracellular fluid pool (i.e., VD < 0.3 L/kg) for which a BSA-based approach is preferable. In contrast, for drugs whose apparent VD exceeds the extracellular fluid space (i.e., VD ≥ 0.3 L/kg), a BW-based approach for dose selection is preferable, which is the most frequently used method in pediatrics. When the pediatric dose for a given drug is not known, these principles can be used to best approximate a proper dose for the initiation of treatment as is illustrated by the following equations:

- Child dose (if VD < 0.3 L/kg) = (child BSA in m²/1.73 m²) × adult dose
- Infant dose (if VD ≥ 0.3 L/kg) = (infant BW in kg/70 kg) × adult dose

It should be noted that this approach assumes that the child’s weight, height, and body composition are age appropriate and normal, and that the “reference” normal adult has a BW and BSA of 70 kg and 1.73 m², respectively. It is useful only for selection of dose size and does not offer information regarding dosing interval because the equations contain no specific variable that describes potential age-associated differences in drug clearance.

In neonates and young infants with developmental immaturity in either GFR and/or ATS, it is often necessary to adjust the “normal” dosing interval (i.e., that used for older infants and children who have attained developmental competence of renal function) for drugs with significant (>50%) renal elimination so as to prevent excessive drug accumulation and possible associated toxicity with administration of multiple doses. To accomplish this therapeutic goal, it is necessary to estimate the apparent T1/2 of the drug.

**Drug-Level Monitoring**

Drug response (either therapeutic or toxic) occurs only as a consequence of drug exposure. Clinically, systemic drug exposure is most commonly evaluated through assessing the plasma drug concentration; a surrogate measurement for a drug reaching its pharmacologic receptor(s).

In the patient, drug-level monitoring can be used to facilitate 2 approaches for evaluating the dose–concentration–effect relationship; therapeutic drug monitoring and pharmacokinetic-based dose individualization (clinical pharmacokinetics). **Therapeutic drug monitoring** largely entails a retrospective, reactive approach whereby drug concentrations in plasma (primarily) or other biologic fluids are measured at some point during either a constant rate intravenous infusion or during a dosing interval for drugs given by intermittent dosing schedules. These levels are then compared with those that are “desired” for a given drug based on published information and used to adjust the dose/dosing regimen in a quasi-empiric fashion. In using a therapeutic drug-monitoring approach, it should be recognized that for many drugs that are therapeutically monitored in the clinical setting (e.g., aminoglycoside antibiotics, vancomycin, phenytoin, phenobarbital, cyclosporine, tacrolimus, mycophenolate mofetil, selected antiretroviral drugs, acyclovir), “desired” plasma concentrations are generally determined from studies in adult patients in whom drug disposition and disease states may be quite different from those in infants and children.

In contrast to therapeutic drug monitoring, **clinical pharmacokinetics** represents a prospective, proactive approach where plasma drug concentrations are used to estimate pharmacokinetic parameters (e.g., apparent Kel, elimination T1/2, apparent VD, total plasma clearance, AUC) which are then used to calculate a dosing regimen required to attain a desired level of systemic exposure (e.g., AUC, steady-state peak and/or trough plasma drug concentrations) that would portend a desired pharmacologic response. Of these 2 approaches, the use of drug-level data for performing clinical pharmacokinetics provides the most optimal approach for individualizing dose/dosing regimen and maintaining some adaptive control over the dose-concentration–effect relationship. This approach is particularly useful for patients who by virtue of their age and/or disease states, may have “abnormal” pharmacokinetics. Approaches used to enable the performance of clinical pharmacokinetics include the manual use of established formulas for calculating pharmacokinetic parameters (generally using a simple 1 compartment open model consequent to the few number of plasma drug-level observations obtained in the context of clinical patient care) or computer-based algorithms (e.g., Bayesian estimation, population-based pharmacokinetic approaches).

Common to both of the aforementioned approaches is the need to accurately assess plasma drug concentrations in a given patient. Figure 60-5 represents a hypothetical general steady-state plasma concentration vs time profile for a drug given by an extravascular route. It is provided to illustrate the following general principles that should be recognized and/or followed when plasma drug-level monitoring is used in patients as a “tool” to individualize drug treatment:

- When a drug reaches a pharmacokinetic steady state (a period corresponding to 5 times the apparent elimination Te/2 for a given drug), both the excursion between the peak (Cmax) and trough (Cmin) plasma concentration and the AUC are identical between dose intervals provided that (1) the dose is not changed; (2) an exact dose-to-dose interval is maintained for drug administration; and (3) the route or rate of drug administration between dosing intervals has not changed.
- Steady-state plasma drug concentrations provide the best surrogate for assessing exposure–response relationships for a given drug.

When used to support clinical pharmacokinetic approaches for dose regimen design, they provide the most accurate estimation of patient-specific pharmacokinetic parameters. Plasma
Drug Formulation and Administration
One of the more unique challenges in pediatric therapeutics is the drug formulation itself. Despite the increasing sensitivity for the need to study drugs in children before they are used in children and to have available “pediatric-friendly” formulations, many drug products that are formulated only for use in adults are routinely given to pediatric patients. Their use can result in inaccurate dosing (e.g., administration of a fixed dose to children with widely varying body weights), loss of desired performance characteristics of the formulation (e.g., crushing a sustained-release tablet or cutting a transdermal patch) and the exposure of infants and children to excipients (e.g., binding agents, preservatives) in amounts capable of producing adverse effects.

Peroral Drug Administration
One of the principal determinants of peroral drug administration in children is the ability to actually get the drug into the body. Peroral formulations are often expelled by children because of poor taste and texture. This is a significant issue, especially when considering that taste sensation differs as a consequence of development and on an interindividual basis. Solid formulations, such as tablets and capsules, are not easily administered to the majority of infants and children owing to their inability to easily and safely swallow them. For example, incomplete development of swallowing coordination may result in choking or aspiration when solid formulations are given to infants and small children. Finally, solid peroral formulations limit the ability for dose titration and dosing flexibility. Drug developers in the United States and abroad are working to address this limitation by the development of new techniques suitable for both oral and peroral drug administration that encompass both products (e.g., dispersible peroral tablets, oral films, titratable granules, oral melts) and drug administration devices (e.g., dosing straws, graduated cylinders for peroral granules).

With regard to dosing accuracy with peroral formulations, liquids (e.g., drops, solutions, syrups, suspensions, elixirs) are preferred for infants and young children. The utility of these formulations is often limited by palatability when taste-masking of the active ingredient(s) cannot be effectively achieved. In the case of suspension formulations, improper reconstitution and/or resuspension prior to dose administration can introduce problems related to accuracy of dosing. Other potential limitations of peroral liquid drug formulations (including those that may be extemporaneously compounded by the pharmacist from drug powder or from solid peroral dosage forms of a given drug) include potential problems related to drug stability, contamination (chemical or bacterial), portability and for some products, the need for them to be refrigerated so as to insure drug stability.

Administration of liquid medications can be associated with risk if the device for administering the medication is not appropriate (e.g., use of a kitchen teaspoon as opposed to a 5.0 mL dosing spoon) or used improperly when measuring a dose that is appropriate for the patient’s age or weight. The low cost and convenience of hypodermic syringes has prompted many physicians and pharmacists to dispense them with liquid medications in order to improve accuracy. Although this approach is seemingly associated with greater accuracy in dosing, parents/caregivers can have difficulty in reading the graduations on a syringe and, also, the plastic caps on the plungers of syringes can produce a choking hazard for infants and young children. All of these problems can be obviated by education of parents/caregivers on how to reliably use special syringes for peroral dosing that pharmacists should dispense with every liquid drug formulation.

Parenteral Drug Administration
In contrast to adults where vascular access is relatively easy to obtain, difficulties are often present in the infant and young child. These are often produced by the smaller diameter of peripheral vessels (relative to the size of the intravenous cannula), developmentally associated differences in body composition (e.g., body fat distribution) and the use of topical anesthetic agents, some of which can produce venous constriction. The small peripheral blood vessels in infants and young children can also limit the volume and rate of intravenous drug administration because of issues of capacity and, in the instance of drugs capable of producing venous irritation, infusion-related discomfort.

An underappreciated issue that can complicate parenteral drug administration to infants occurs when the concentration of a given drug formulation does not enable accurate measurement of dose. Errors consequent to improper dilution of adult formulations necessary to ensure appropriate osmolality and volume for IV administration (the most common resulting in a 10-fold overdose) are not uncommon. For example, morphine, a drug commonly used in neonates, infants, and children, is commonly available in a 2 mg/mL...
concentration. A usual 0.1 mg/kg morphine dose for a 1 kg infant using this formulation would require a nurse or pharmacist to accurately withdraw 0.05 mL and administer it into a length of IV tubing with a dead space volume that may exceed that of the dose by approximately 100-fold. In this situation, accuracy of dose and infusion time can be significantly compromised. Although underdosing is often a serious problem when attempting to administer very small volumes, overdoses also occur, owing to inaccurate extemporaneous dilutions. Moreover, attempts to compensate for the volumes present within the IV tubing further predispose the patient to receive an incorrect, possibly unsafe, dose. Whenever such concentrated drug formulations are the only source for use, appropriate alteration of the stock parenteral solution should be performed and manufactured by the pharmacy department. As well, many errors can be avoided by the use of standard dilutions that all practitioners are aware of and using standardized approaches for IV drug administration that minimize complications associated with unrealized drug dilution and errant infusion times (e.g., pediatric syringe pumps attached to low-volume tubing).

Although used rather infrequently, IM drug administration offers a route of administration for many drugs in those instances where venous access is not immediately available or when a therapeutic drug regimen involves use of a single or limited number of doses. Although appealing with respect to immediacy, this route of administration can be associated with problems (e.g., muscle and/or nerve damage, sterile abscess formation, variable rate of drug absorption consequent to developmental differences in vascular perfusion of muscle beds), especially in the neonate and small infant. Finally, the decision to utilize the IM route must take into consideration the physicochemical properties (e.g., pH, osmolarity, solubility) of the drug formulation and/or any diluent used to prepare it.

Other Routes for Drug Administration
Neonates, infants, children, and adolescents with certain pulmonary conditions (e.g., reactive airway disease, viral-induced bronchiolitis, asthma, cystic fibrosis) frequently receive drugs (e.g., corticosteroids, β-adrenergic agonists, antimicrobial agents, mucolytic drugs) via inhalation. The pulmonary surface area in pediatric patients of all ages is a very effective, easily traversable barrier for drug absorption. Rate-limiting factors for pulmonary drug absorption include physicochemical factors associated with the drug and delivery system (e.g., particle size, diffusion coefficient, chemical stability of drug molecule in the lung) and physical factors that influence intrapulmonary drug deposition (e.g., active vs passive drug delivery to the tracheobronchial tree, respiratory minute volume, internal airway diameter); many of which are developmentally determined. For drugs formulated for delivery using a metered-dose inhaler (either drug powder or suspended particles using a carrier gas), developmental factors (e.g., incoordination of device actuation with inhalation, inability to follow instructions for clearing of airway, and passive inhalation with actuation of delivery device) either prevent their use (such as in infants and small children) or limit the bioavailability of the drug to be administered. In these instances, specific devices (e.g., masks, spacer chambers) and/or methods of delivery (e.g., continuous aerosolization via mask) can be used to improve the efficiency of drug delivery and, thereby, drug efficacy.

In pediatric patients, percutaneous drug administration is generally reserved for agents intended to produce a local effect within the dermis. Development has an impact on the barrier of the skin that, if not recognized and controlled for, can produce situations in which systemic toxicity can result (see “Drug Absorption” above). Similar therapeutic challenges occur when transmucosal routes (e.g., buccal, sublingual, rectal) are used for drug administration. Specifically, unpredictable systemic bioavailability may complicate treatment consequent to variability in the rate and/or extent of drug absorption. Finally, direct intraosseous drug administration via puncture of the tibia is occasionally used in infants and small children for administration of drugs and crystalloid fluids given acutely during resuscitation efforts. It is particularly useful when vascular access sufficient for drug administration cannot be immediately accomplished as the onset of action by this route is comparable with that seen after IV administration.

Adherence and Compliance
Beyond proper individualization of drug dose based on developmental considerations, the influence of concomitant disease/treatment and the selection of the proper drug formulation, the success of drug treatment in a pediatric patient is inextricably linked to the successful administration of the drug. Physical and cognitive immaturity makes the infant and the child a dependent creature in almost all respects, including those related to therapeutic drug administration. Until a child reaches an age at which they can physically self-administer a drug in an accurate, proficient fashion and can mentally assume responsibility for this task (generally from 7-14 yr of age, depending on the individual child), compliance with a drug regimen becomes the responsibility of an adult. In a hospital environment, compliance is ensured through the actions of physicians, nurses, and pharmacists who, collectively through an integrated system of medical care, assume this responsibility. Upon discharge, the responsibility is transferred to parents/guardians or other adult caregivers in an environment that is generally nonmedical. At this juncture, therapeutic compliance morphs into adherence as defined by the potential for conflicting demands (e.g., multiple adult caregivers; different external environments such as home, daycare, school; parents tending to the needs of multiple children) to introduce variability (anticipated and unpredictable) in drug administration. Whether treatment is for a self-limiting (e.g., antibiotic administration) or chronic (e.g., asthma, diabetes) condition, challenges to therapeutic adherence have the potential to serve as primary determinants of drug safety and efficacy in infants and young children.

In contrast to the period encompassing infancy and childhood, adolescence poses its own unique challenges to therapeutic adherence. During this period, psychosocial maturation almost always lags behind physical maturation. Development of cognitive and physical skills in most adolescents enables them to self-administer a prescribed medication in a proper manner with little to no supervision. However, psychodynamic issues experienced by a substantial number of adolescents (e.g., complete understanding of the ramifications of undertreatment, disease progression, and/or roles of disease prevention, and/or health maintenance; perceptions of immortality and the associated lack of need for treatment; disorganized patterns of thinking capable of confounding treatment schedules; defiant/oppositional behavior toward authority figures) can often precipitate therapeutic failure, through either undertreatment or overtreatment, the latter occasionally leading to drug toxicity. Unfortunately, the only maneuver that can be used to facilitate therapeutic compliance and adherence in the pediatric patient is the combination of vigilance (on behalf of all caregivers) and repetitive education coupled with positive reinforcement (e.g., the use of motivational interviewing techniques). When children reach the age of consent (i.e., generally by 7 yr of age in children who have normal neurobehavioral development), they have the beginning level of cognitive ability sufficient to engender understanding about their medical condition(s) and how effective treatment can be used to improve their life. Through diligent efforts placed toward patient education and reeducation, older children and adolescents can assume a level of responsibility for active partnership in their overall medical management, one that will mature as educational efforts, driven by a shared desire for an optimal outcome, are regularly made. The pediatrician’s role in fostering this is paramount given their understanding of development and the regular patient–parent interactions that occur from birth through adolescence.

Drug–Drug Interactions
Pharmacokinetic and/or pharmacodynamic properties of drugs may be altered when 2 or more drugs are coadministered to a patient (refer to Table 60-6). Even though many interactions occur at the level of drug metabolism, they may also occur at the level of drug absorption (e.g., inhibition of intestinal CYP3A4 activity by grapefruit juice or St. John’s wort) and consequent reduction in presystemic clearance of
CYP3A4 substrates), distribution (e.g., displacement of warfarin plasma protein binding by ibuprofen with consequent increased hemorrhagic risk), or elimination (e.g., inhibition of ATS of β-lactam antibiotics by probenecid). Drug–drug interactions may also occur at the level of the receptor (via competitive antagonism), many of which are intentional and produce therapeutic benefit in pediatric patients (e.g., antihistamine reversal of histamine effects, many of which are predictable based on a priori knowledge of a given drug's biotransformation profile). Although such information can be derived from the primary literature, it may not be immediately translated into a useful clinical context consequent to limitations associated with in vitro to in vivo extrapolation, which can (1) use of animal models for characterizing metabolism; (2) extrapolating enzyme kinetics derived from pooled human liver microsomes or recombinant human drug-metabolizing enzymes to estimates of in vivo drug clearance; (3) extrapolating in vitro data obtained from fully competent (i.e., adult activity) hepatic microsomes to estimates of clearance in patients who may have developmental and/or disease-associated compromise in enzyme activity; (4) inaccurate accounting for pharmacogenetic variation in drug-metabolizing activity (i.e., constitutive activity); (5) the contribution of multiple different drug-metabolizing enzymes in the overall biotransformation of a given drug (i.e., a polyfunctional drug substrate); (6) the potential role of enzyme induction or inhibition in vivo that is not reflected from conditions used for in vitro metabolism studies.

Despite these limitations, information pertaining to drug–substrate interaction can be useful in ascertaining the direction (e.g., enzyme inhibition → reduced clearance → higher plasma drug concentration → enhanced effect as compared to enzyme induction → increased clearance → reduced plasma drug concentration → diminished effect) of a drug–drug interaction. Although multiple sources describing specific drug–drug interactions exist (e.g., primary and secondary literature, drug product labeling), the information may not be complete or updated. In examining multiple information sources pertaining to this topic, the authors found a data compilation from Indiana University (http://medicine.iupui.edu/clinpharm/ddis/) to be the most complete and clinically useful. Utilizing primary literature should be assessed when information is not available in online sources.

Drug interactions may also occur at a pharmaceutical level as a result of a physicochemical incompatibility of two medications when combined. Such interactions generally alter the chemical structure of 1 or both constituents, thereby rendering them inactive and potentially dangerous (e.g., intravenous infusion of a crystalline precipitate or unstable suspension). For example, ceftriaxone should be avoided in infants younger than 28 days of age if they are receiving or are expected to receive intravenous calcium-containing products because of reports of neonatal deaths resulting from crystalline deposits in the lungs and kidneys. Alternatively, 2 drugs simultaneously administered perorally may form a complex that can inhibit drug absorption (e.g., coadministration of doxycycline with a food or drugs containing divalent cations).

Nonprescription preparations, herbal supplements, and certain foods also have the potential to produce interactions with drugs. These are often quite challenging for the clinician, especially for alternative therapies, in that their composition (or potency) may not be completely discernable from the product labels and because the disposition of many natural products has not been studied in either children or adults. Many patients and their parents also do not consider alternative

**PHARMACOKINETIC**

- **Absorption**
  - *Inhibition of MDR1*: Amiodarone and digoxin
    - *Complex formation*: Quinolone and tetracycline antibiotics with divalent/trivalent cations (e.g., Ca²⁺, Mg²⁺, Fe³⁺, Al³⁺)
    - Mycophenolate mofetil plus antacids
    - *Pharmaceutical preparations*: Ceftriaxone with IV fluids containing calcium
  - *Distribution*: Ceftriaxone + endogenous bilirubin
    - NSAID plus warfarin
  - *Metabolism*:
    - *Induction*: Rifampin plus antiretrovirals
    - *Inhibition*: Azole antifungals plus CYP3A4 substrates
  - *Elimination*: Penicillin plus probenecid
    - Methotrexate plus aspirin

- **Increased digoxin concentration, digoxin toxicity (↓ digoxin 50%)**
- **Decreased antibiotic absorption**
- **Decreased absorption of mycophenolate mofetil**
- **Crystalline deposits in lungs/kidneys of neonates**
- **Displacement of bilirubin from albumin binding site, increased risk kernicterus in neonates**
- **Displacement of warfarin from albumin binding site with consequent exaggerated anticoagulant response**
- ** Decreased serum concentration of antiretroviral because of induced CYP metabolism**
- **↑ Drug levels because of inhibition of CYP3A4-mediated metabolism resulting in drug toxicity**
- **Decreased tubular secretion of penicillin resulting in increased serum concentrations**
- **Inhibition of renal tubular secretion of methotrexate resulting increased methotrexate concentration**

This table is not meant to be an all-inclusive list of drug–drug interactions. Care should be taken when prescribing all medications, and the potential of interactions should be considered. The practitioner is encouraged to assess the possibility of all interactions when prescribing medications.

NSAID, nonsteroidal antiinflammatory drug.

Adverse Drug Reactions

Adverse drug reactions (ADRs) have been defined by the World Health Organization as “a response to a drug that is noxious and unintended, and occurs at doses normally used for the prophylaxis, diagnosis, therapy or treatment of disease or for the modification of physiological functions.” There are 2 traditional pharmacologic classifications of ADRs: type A and type B. Type A reactions are dose dependent, predictable, and account for 85-90% of all ADRs. These are often considered as “side effects” to medications. Type B reactions are not dose dependent, are unpredictable and account for approximately 10-15% of all adverse reactions. These are generally considered to represent hypersensitivity (i.e., allergic) reactions whereas some can have a non-immune basis. Historically, such standardized definitions describing adverse events have not been routinely utilized. Furthermore, patients sometimes misinterpret some side effects as allergies (e.g., diarrhea with amoxicillin/clavulanate) and this may be perpetuated through the patient’s medical record, thus potentially restricting a useful and necessary medication.

In the pediatric population, ADRs are common occurrences that produce a major burden to patients and the healthcare system. Studies concerning ADRs in pediatric patients suggest the following: (1) approximately 9% of all pediatric patients admitted to the hospital experience an ADR during their treatment; (2) the apparent incidence of ADRs in children in outpatient clinics is approximately 1.5%; (3) ADRs have been reported as being responsible for >2% of pediatric admissions to children's hospitals; and (4) approximately 40% of ADRs occurring in hospitalized children are potentially life-threatening. In considering these “statistics” it should be recognized that the true incidence of ADRs in children is not known as a consequence of generalized underreporting by healthcare providers (physicians, nurses, pharmacists), parents/caregivers, and patients (who may not recognize signs/symptoms and/or be unable to report them), and in many countries (including the United States), the lack of a standardized surveillance and real-time reporting system. As a consequence, estimation of their incidence relies upon spontaneous, volunteer reporting systems that lack uniformity and critical evaluation and do not provide both numerator and denominator data necessary to determine true incidence of a specific ADR in a specific subpopulation of patients.

Despite the limitations associated with determining the incidence of ADRs in children, it is estimated that their occurrence in patients 0-4 yr of age (3.8%) is more than double that seen at any other time throughout childhood and adolescence. The reasons for this are not currently known but may involve developmental differences in pharmacokinetics and/or pharmacodynamics (i.e., altered dose-concentration–effect relationship), age-associated differences in physiologic “systems” that modulate drug and/or metabolite-mediated cellular injury (e.g., the immune system) and/or the therapeutic use of drugs known to have a relatively high incidence of producing ADRs (e.g., delayed hypersensitivity reactions associated with β-lactam antibiotics). Also, it is important to recognize that infants can experience ADRs from drugs that are not administered to them therapeutically, but from incidental drug exposure (e.g., transplacental drug passage, breastfeeding). Examples include neonatal abstinence syndrome associated with maternal opiate use, production of a hyperserotonergic state in neonates born to mothers who received selective serotonin reuptake inhibitors during and through pregnancy, and opiate toxicity in breastfed infants whose mothers were taking codeine for pain management. In these instances, drug accumulation occurring because of reduced activity of drug-metabolizing enzymes associated with development, and, potentially, pharmacogenetically determined phenotypic changes that, in concert, can produce a level of systemic drug exposure sufficient to produce exaggerated drug response or frank toxicity.

There are also specific ADRs that occur at a much greater frequency in infants and children as compared to adults. Examples include aspirin-associated Reye syndrome, cefaclor-associated serum sickness-like reactions, lamotrigine-induced cutaneous toxicity, and in infants younger than 2 yr of age, valproic acid–induced hepatotoxicity. It is not clear whether the age prediction for these specific ADRs is associated with developmental differences in drug biotransformation related to both metabolite formation and detoxification or, alternatively, has a pharmacogenetic basis. Finally, it should be recognized that children, like adults, do experience hypersensitivity reactions to drugs. Examples include reactions to anticonvulsant drugs (e.g., phenytoin, carbamazepine, valproate), sulfonamides (e.g., sulfamethoxazole, sulfadiazine), minocycline, cefaclor, and abacavir. These specific ADRs are not characteristic of type I (i.e., immediate) hypersensitivity reactions (e.g., true penicillin allergy) or anaphylactoid reactions; rather, they represent delayed hypersensitivity reactions that are classified as idiosyncratic with respect to their origin. A relatively common constellation of symptoms (fever, rash, and lymphadenopathy) suggests that abnormal activation/regulation of the immune system is a predominant component of their pathogenesis. Data from in vitro studies of sulfamethoxazole hypersensitivity also support this assertion. A requisite role for metabolic bioactivation (for anticonvulsants, sulfamethoxazole, and cefaclor) and, possibly, genetic factors, such as allelic variants in HLA-B (e.g., HLA-B*5701 and HLA-B*1502 associated with hyper-sensitivity reactions to abacavir and carbamazepine) appear also to be involved in their etiology.

PERSONALIZED MEDICINE

See also Chapter 59.

The general concept of personalized medicine involves the application of genomic information to predicting a disease, disease severity, and therapeutic response. This “new vision of medicine” has been described as the 3 Ps: predictive, personalized, and preventive. However, in children, ontogeny should also be considering when
discussing personalizing therapeutic treatments. Thus, the aim of pediatric personalized medicine is to uniquely combine genetic variation with developmental stage to provide a tailored approach to either drug avoidance (in the case of predicted, significant risk of an ADR) or treatment.

The primary purpose of general anesthesia is to suppress the conscious perception of, and physiologic response to, noxious stimuli and to render the patient unconscious. Potent drugs are used to blunt physiologic responses to what would otherwise be life-threatening trauma (surgery). Intraoperatively, the anesthesiologist is responsible for providing analgesia as well as physiologic and metabolic stability (Table 61-1). This responsibility is facilitated by obtaining an adequate preanesthesia history (Table 61-2). Although anesthetic risk has greatly decreased, the increased risk of morbidity and mortality in the perioperative period demands the utmost vigilance. The risk is even higher in certain disease states (Table 61-3).

### GENERAL ANESTHESIA

**Analgesia**

Providing analgesia for procedures both in and out of the operating room is a major responsibility and function within a spectrum of care (Table 61-4). Techniques exist to provide profound pain relief during operative procedures for all patients, including the most critically ill infants. Blunting the physiologic responses to painful stimuli inhibits the stress response and its multiple deleterious physiologic and metabolic consequences. The response to painful and stressful stimuli is a potent stimulus of the systemic inflammatory response syndrome, which leads to increased catabolism, physiologic instability, and increased mortality (see Chapter 70). Appropriate use of medication, such as fentanyl anesthesia in neonates, reduces the incidence of postoperative bradycardia, hypotension, acidosis, intraventricular hemorrhage, coagulation abnormalities, hypoglycemia, and death.

**Hypnosis and Amnesia**

The blunting of both consciousness (hypnosis) and conscious recall (amnesia) is a crucial feature of pediatric anesthesia care. Awareness of painful, anxiety-provoking, and stressful conditions for children is

Definitions of Anesthesia Care

### MONITORED ANESTHESIA CARE
A specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.

Monitored anesthesia care includes all aspects of anesthesia care: a preprocedure assessment, intraprocedure care, and postprocedure anesthesia management.

During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, which may include some or all of, but are not limited to, the following:

- Discussing anesthesia care with the family and child, obtaining consent, allaying anxiety and answering questions—family centered anesthesia care.
- Monitoring of vital signs, maintenance of the patient’s airway, and continual evaluation of vital functions.
- Diagnosing and treating clinical problems that occur during the procedure.
- Administering sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary to ensure patient safety and comfort.
- Providing other medical services as needed to accomplish the safe completion of the procedure.

Anesthesia care often includes the administration of medications for which the loss of normal protective reflexes or loss of consciousness is likely.

**Monitored anesthesia care** refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure.

If the patient is rendered unconscious and/or loses normal protective reflexes for an extended period, this is considered a general anesthetic.

### LIGHT SEDATION
Administration of anxiolysis and/or analgesia that obtunds consciousness but does not obtund normal protective reflexes (cough, gag, swallow, hemodynamic reflexes), or spontaneous ventilation.

### DEEP SEDATION
Sedation that obtunds consciousness and normal protective reflexes or possesses a significant risk of blunting normal protective reflexes (cough, gag, swallow, hemodynamic reflexes), hemodynamic and respiratory insufficiency may occur.

### GENERAL ANESTHESIA
Administration of hypnosis, sedation, and analgesia that results in the loss of normal protective reflexes.

### REGIONAL ANESTHESIA
Induction of neural blockade (either central, neuraxial, epidural, or spinal; or peripheral nerve block, e.g., digital nerve block, brachial plexus block), which provides analgesia and is associated with regional motor blockade.

Consciousness is not obtunded.

Special expertise is required.

Frequently, in children, anxiolysis and sedation are also necessary for this technique to be successful.

Regional anesthesia (e.g., caudal epidural blockade) is used to supplement general anesthesia and provide postoperative analgesia.

### LOCAL ANESTHESIA
Provision of analgesia by local infiltration of an appropriate anesthetic agent.

Does not require the presence or involvement of an anesthesiologist, although an anesthesiologist may provide local anesthesia services.

### NO ANESTHESIOLOGIST
An anesthesiologist will not be involved in the care of the child in any way.

</table>
| MONITORED       | Provides other medical services as needed to accomplish the safe completion of the procedure.
| ANESTHESIA      | Administering sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary to ensure patient safety and comfort. |
| CARE            | Diagnosing and treating clinical problems that occur during the procedure.                    |
| LIGHT           | Sedation that obtunds consciousness but does not obtund normal protective reflexes.          |
| SEDATION        | Administration of anxiolysis and/or analgesia that obtunds consciousness but does not obtund normal protective reflexes. |
| DEEP            | Sedation that obtunds consciousness and normal protective reflexes or possesses a significant risk of blunting normal protective reflexes. |
| GENERAL         | Administration of hypnosis, sedation, and analgesia that results in the loss of normal protective reflexes. |
| ANESTHESIA      | Induction of neural blockade (either central, neuraxial, epidural, or spinal; or peripheral nerve block, e.g., digital nerve block, brachial plexus block), which provides analgesia and is associated with regional motor blockade. |
| CARE            | Consciousness is not obtunded. Special expertise is required. Frequently, in children, anxiolysis and sedation are also necessary for this technique to be successful. Regional anesthesia (e.g., caudal epidural blockade) is used to supplement general anesthesia and provide postoperative analgesia. |
| LOCAL           | Provision of analgesia by local infiltration of an appropriate anesthetic agent.               |
| ANESTHESIA      | Does not require the presence or involvement of an anesthesiologist, although an anesthesiologist may provide local anesthesia services. |
| CARE            | An anesthesiologist will not be involved in the care of the child in any way.                  |

---

Just as deleterious, physically and psychologically, as the painful procedures themselves. Management is aimed at blunting the fear and emotional response during surgery, painful procedures (bone marrow aspiration, lumbar punctures), or nonpainful but anxiety-provoking procedures (MRI, CT). Many drugs provide anxiolysis, blunting of recall, and amnesia for such events (Table 61-5). Obtundation of consciousness may accompany the provision of analgesia. Hypnotic and sedative agents can induce altered consciousness without producing any analgesia; analgesia and obtunded consciousness are not synonymous. It is also possible to provide analgesia (local, spinal, or epidural analgesia) without obtunding consciousness.

**Sedation** describes a medically induced state that is on a continuum between the fully alert, awake state and general anesthesia (see Table 61-4). In addition to inducing unconsciousness and amnesia, general anesthesia obtunds or ablates critical physiologic reflexes; the most important are airway-protective reflexes: coughing, gagging, and swallowing. Cardiorespiratory reflexes are also obtunded with general anesthesia; respiratory depression and hemodynamic compromise may occur and may be profound. As sedation deepens toward general anesthesia, loss of airway patency, loss of airway-protective reflexes, and loss of cardiovascular stability occur. Light (minimal) sedation is anxiolysis without loss of these reflexes or airway patency. Deep sedation occurs when these reflexes are obtunded or lost (see Table 61-4). Adequate sedation in children may be accompanied by the actual or potential loss of vital reflexes. It is mandatory that those providing sedation for a child be able to detect the transition into deep sedation and general anesthesia and be prepared to manage the child’s airway and circulation, and provide CPR if required.

**Akinesia (Immobility or Muscular Relaxation)**

Akinesia is the absence of movement. It is necessary to ensure safe and adequate operative conditions and to provide ideal conditions for advanced and meticulous surgery. Akinesia is often produced with muscle relaxants (see Table 61-5). These agents facilitate respiratory management in the perioperative period and in critically ill patients. The absence of movement is neither the absence of pain nor the presence of amnesia. **Whenever neuromuscular blocking agents are used, analgesia and sedation must be provided.**

**Physiologic Support**

The need for anesthesia increases the need to monitor and support physiologic integrity and homeostasis. Sedation and anesthesia have significant and potentially life-threatening physiologic consequences (see Tables 61-4 and 61-5). Maintenance of adequate cardiopulmonary function, fluid management, electrolyte control, thermoregulation, and concern for all aspects of the child’s health are critical during anesthesia.

**Vigilance**

Constant, critical attention by physicians who understand the demands of the surgical procedure, as well as the changes in physiologic status and their implications, is mandatory to provide safe perioperative care.

<tr>
<td><strong>DRUG</strong></td>
<td><strong>USES AND IMPLICATIONS</strong></td>
</tr>
<tr>
<td><strong>MUSCLE RELAXANTS</strong></td>
<td></td>
</tr>
</tbody>
</table>
| Succinylcholine | Used to facilitate endotracheal intubation and maintain muscle relaxation in emergency situations; now virtually never given routinely  
| | A depolarizing neuromuscular blocking agent with rapid onset and offset properties  
| | Associated with the development of malignant hyperthermia in susceptible patients  
| | Degraded by plasma cholinesterase, which may be deficient in some individuals; such a deficiency may result in prolonged effect  
| | Fasciculations may be associated with immediate increases in intracranial and intraocular pressures as well as postoperative muscle pain  
| | Nondepolarizing neuromuscular blockers  
| | Vecuronium, rocuronium, mivacurium, cis-atracurium, all aminosteroids  
| | Have less-rapid onset than succinylcholine but are longer-acting  
| | Prolonged ICU use may lead to profound muscle weakness  
| | Vecuronium and rocuronium are metabolized by the liver and excreted in bile; they are the most commonly used neuromuscular blocking agents  
| | cis-Atracurium is metabolized by plasma cholinesterase and therefore may be of benefit in patients with hepatic or renal disease |
| **HYPNOTICS** |                       |
| Propofol | Rapidly acting hypnotic; amnestic, but not analgesic, a general anesthetic agent  
| | Like pentothal, may cause hypotension  
| | Causes respiratory depression  
| | May increase the seizure threshold  
| | Great utility in titrated doses for sedation and with local anesthetic and short-acting opioid for outpatient procedures  
| | May suppress nausea  
| | Associated with the often fatal propofol infusion syndrome when used in prolonged intravenous infusion (>24 hr) and therefore not used for ICU sedation in children  
| Etomidate | Cardiovascular stability on induction with no increase in intracranial pressure  
| | Inhibits corticosteroid synthesis and increases ICU mortality  
| | Associated with myoclonus, potential difficulty with assisted ventilation, and pain on injection  
| Ketamine | Hypnotic analgesic and amnestic  
| | Causes sialorrhea and should be coadministered with an antisialagogue, such as atropine or glycopyrrolate  
| | May be associated with laryngospasm  
| | Causes endogenous catecholamine release, tachycardia, and bronchodilation  
| | Increases intracranial and intraocular pressures  
| | Decreases the seizure threshold  
| **SEDATIVE–ANXIOLYTICS** |                       |
| Benzodiazepines | Produce sedation, anxiolysis, or hypnosis, depending on the dose  
| | May produce antegrade, but not retrograde, amnesia  
| | All agents raise the seizure threshold, are metabolized by the liver, and depress respiration, especially when administered with opioids  
| | Frequently administered as premedications  
| | Diazepam may be painful on injection and has active metabolites  
| | Midazolam can be administered by various routes and has a short half-life  
| | Lorazepam has no active metabolites  
| | Sedation effected by all benzodiazepines may be reversed by flumazenil, but respiratory depression may not be reliably reversed  
| Dexmedetomidine | Produces anxiolysis, sedation, sympatholysis, by $\alpha_2$-receptor stimulation centrally; has mild analgesic properties  
| | Side effects include hypotension and bradycardia  
| | Commonly used for procedural and ICU sedation  
| | Continuous infusion for ICU sedation; currently limited to 24 hr  
| **ANALGESIC–SEDATIVES** |                       |
| Opioids | Gold standard for providing analgesia  
| | All cause respiratory depression  
| | Morphine and, to a lesser extent, hydromorphone may cause histamine release  
| | The synthetic opioids fentanyl, sufentanil, and short-acting alfentanil may have a greater propensity to cause chest wall rigidity when administered rapidly or in high doses and are also associated with the rapid development of tolerance; these 3 drugs have particular utility in cardiac surgery because of the hemodynamic stability associated with their use  
| | Remifentanil is an ultra–short-acting synthetic opioid that is metabolized by plasma cholinesterase; it may have particular utility when deep sedation and analgesia are required along with the ability to assess neurologic status intermittently  
| **INHALATIONAL AGENTS** |                       |
| Nitrous oxide | Causes amnesia and mild analgesia at low concentrations  
| | Danger of hypoxic mixture if the oxygen concentration is not monitored and preventive safety mechanisms are not in place  
| | “Complete anesthetics”—they induce a state of hypnosis, analgesia, and amnesia  
| | All are myocardial depressants, and some are vasodilators  
| | May trigger malignant hyperthermia in susceptible individuals  
| Potent vapors, sevoflurane, desflurane, isoflurane | Sevoflurane is almost universally used for inhalation induction of anesthesia in children  
| | All are bronchodilators at equipotent concentrations  
| | Isoflurane, and especially desflurane are associated with a higher incidence of laryngospasm, when used for anesthetic induction, than sevoflurane  
| | Causes amnesia and mild analgesia at low concentrations  
| | Danger of hypoxic mixture if the oxygen concentration is not monitored and preventive safety mechanisms are not in place  
| | “Complete anesthetics”—they induce a state of hypnosis, analgesia, and amnesia  
| | All are myocardial depressants, and some are vasodilators  
| | May trigger malignant hyperthermia in susceptible individuals  
| | Sevoflurane is almost universally used for inhalation induction of anesthesia in children  
| | All are bronchodilators at equipotent concentrations  
| | Isoflurane, and especially desflurane are associated with a higher incidence of laryngospasm, when used for anesthetic induction, than sevoflurane |
for all children. Careful attention to a child’s preoperative condition is mandatory for minimizing the risk during perioperative care (see Tables 61-3 and 61-4).

**INDUCTION OF GENERAL ANESTHESIA**

The goal of induction of general anesthesia is to rapidly achieve surgical anesthesia by using IV or, more commonly in children, inhalational induction agents. In children who are too young to tolerate the establishment of vascular access before the induction of anesthesia, it is routine to induce anesthesia by mask inhalation of volatile anesthetics. In the operating room, a child is often accompanied by the parents (parental presence during induction [PPPI]) and placed on the operating room table. Before the induction of anesthesia, monitors are usually applied to the child. These include a pulse oximeter, electrocardiogram, and a blood pressure cuff. The child is then cautiously introduced to the face mask, which contains a high gas flow (5-7 L/min of oxygen), frequently mixed with nitrous oxide. Inhalation of nitrous oxide and oxygen for 60-90 sec induces a state of euphoria. The airway responses to inhalational anesthetics are now blunted, and sevoflurane can be introduced into the inhaled gas mixture. This leads to unconsciousness within 30-60 sec while the child continues to breathe spontaneously.

The child is now “asleep,” and the parents can be asked to leave. An IV line is then started, and comprehensive intraoperative monitoring initiated. Surgical anesthesia can be maintained by spontaneous ventilation with a mask; this is safe only when the airway is secure and patent, the stomach is empty, and the child is older than 6 mo of age. Procedures longer than 1 hr are not usually performed with mask inhalational anesthesia. If these conditions are not met, if the surgeon needs to approach the airway, or if muscular paralysis is required, then the airway must be secured with endotracheal intubation. Although endotracheal intubation can be performed under deep inhalational anesthesia with respiratory depression and obtunded cough and gag reflexes, the depth of anesthesia required to ablate airway reflexes is very close to the level that induces hemodynamic instability. Therefore, muscle relaxation with IV, nondepolarizing muscle relaxants is induced to facilitate endotracheal intubation. Succinylcholine is rarely, if ever, used. After paralysis is induced, direct laryngoscopy and airway intubation can be performed. Correct endotracheal tube placement is confirmed by direct laryngoscopy, end-tidal CO₂ measurement, endotracheal tube fogging, and the finding of bilaterally equal breath sounds during positive-pressure ventilation. If necessary, fiberoptic airway endoscopy and chest radiograph, in addition to these measures, can be used to confirm correct endotracheal tube placement.

After endotracheal intubation, spontaneous ventilation may be permitted, if muscle relaxants are not used or have worn off; it is routine to provide controlled mechanical ventilation. When the child is completely anesthetized, positioned for surgery, and hemodynamically stable, and maintenance anesthesia is achieved, the surgery can begin.

**Inhalational Anesthetics**

General anesthesia may be induced and maintained by either inhalation or the IV route. The inhalational anesthetics used in children include sevoflurane, isoflurane, and desflurane. Although halothane is the prototypical pediatric inhalational anesthetic agent, it has been replaced by sevoflurane and is no longer used in the United States. The minimal alveolar concentration (MAC) of an inhalational anesthetic is the alveolar concentration (expressed as percent at 1 atmosphere) that provides sufficient depth of anesthesia for surgery in 50% of patients. For potent inhalational agents, the alveolar concentration of an anesthetic reflects the arterial concentration of anesthetic in the blood perfusing the brain. Thus, the MAC is an indication of anesthetic potency and is analogous to the ED₉₀ (effective dose in 50% of recipients) of a drug. MAC is age-dependent, is lower in premature infants than in full-term infants, and decreases from term through infancy to preadolescence. In adolescence, MAC again increases, falling thereafter. Inhalational anesthetic agents are poorly soluble in blood but rapidly equilibrate between alveolar gas and blood.

**Respiratory Effects**

The advantages of inhalational anesthesia are rapid onset, rapid offset, convenient route of delivery and excretion (respiratory), and the ability to provide profound analgesia and amnesia. Inhalational anesthetics are all airway irritants and, in low doses, can cause laryngospasm. All inhalational anesthetics depress ventilation in a dose-dependent manner. Thus, expired CO₂ and PaCO₂ (arterial partial pressure of carbon dioxide) increase in spontaneously breathing children. In addition, anesthesia also decreases end-expiratory lung volume. Small lung volumes result in a decrease in lung compliance, increases in total pulmonary resistance, work of breathing, and intrapulmonary arteriovenous shunting, and a restrictive lung defect. Inhalational anesthetics also shift the CO₂ response curve to the right, thus decreasing, but not abating, the increase in minute ventilation with increasing PaCO₂.

Inhalational anesthetics, which may induce apnea and hypoxia in premature infants and newborns, are less frequently used in premature infants and children. In neonates and young infants, general anesthesia always necessitates endotracheal intubation and controlled mechanical ventilation. In older children, spontaneous breathing through a mask or a laryngeal mask airway without controlled ventilation is possible for shorter operations. The decreased end-expiratory lung volume and increased work of breathing always necessitate higher inspired oxygen tension.

**Cardiovascular Effects**

Cardiovascular effects of inhalational anesthesia include depressed cardiac output and peripheral vasodilation; hypotension is frequent. This is accentuated in hypovolemic patients. This hypotensive effect is more pronounced in neonates than in older children and adults. Inhalational anesthetics also decrease baroreceptor and heart rate responses. Inhalational anesthesia blunts the hypoxic pulmonary vasmotor response in the pulmonary circulation, an effect that may contribute to hypoxemia.

The net effect of inhalational anesthesia is decreased oxygen delivery. Perioperatively, catabolism is enhanced and oxygen demand is increased; there may be a profound imbalance between oxygen demand and oxygen delivery. Development of a metabolic acidosis intraoperatively may reflect this imbalance. Because the cardiovascular depressant effects of inhalational anesthesia are greater in premature and newborn infants, these agents are of limited use in such patients.

All inhalational anesthetic agents cause cerebrovasodilation. Sevoflurane is a more potent cerebrovasodilator than isoflurane. Thus, in children with elevated intracranial pressure, impaired cerebral perfusion, or head trauma, and in premature neonates at risk for intraventricular hemorrhage, inhalational anesthetics should be used with extreme caution. Although inhalational anesthetics decrease cerebral oxygen consumption, they may disproportionately decrease blood flow; thus worsening oxygen delivery.

**Specific Anesthetics**

**Sevoflurane**

Sevoflurane is the most commonly used inhalational anesthetic in children for both induction and maintenance of general anesthesia. It is not a significant airway irritant and leads to smoother induction than isoflurane. Emergence from sevoflurane anesthesia is quite rapid; there is a significant amount of emergence delirium, especially if pain has been inadequately controlled or induction was stormy and preoperatively anxiety high. This effect can be blunted by pretreatment with midazolam and adequate use of opioids, although the latter delay recovery from anesthesia. Metabolism of sevoflurane yields free fluoride, which may cause renal damage; consequently, the FDA has restricted the use of sevoflurane to <2 MAC hr, preferably with fresh gas flow rates >2 L/min.

**Isoflurane**

Isoflurane maintains cardiac output and cerebral perfusion more effectively than sevoflurane. Isoflurane is pungent and a significant airway irritant, with an unacceptably high incidence of complications, such as laryngospasm during induction. Emergence from anesthesia with
isoflurane is quite smooth, but slower than for sevoflurane. Cerebral blood flow is only minimally affected, and cerebral oxygen delivery is maintained. Because isoflurane is not a suitable induction agent, induction with sevoflurane or with an intravenous agent, and maintenance with isoflurane is a common pediatric anesthesia practice.

Desflurane
A potent airway irritant, desflurane causes coughing, breath holding, and laryngospasm during induction and therefore is unsuitable for induction. It is frequently used for maintenance of anesthesia, and emergence from desflurane anesthesia is rapid.

Nitrous Oxide
Nitrous oxide is a tasteless, colorless, odorless gas with potent analgesic properties. It induces a state of euphoria (hence its nickname, “laughing gas”). The MAC of nitrous oxide is >100; consequently, it is not suitable as a sole agent to maintain anesthesia. Nevertheless, nitrous oxide has few complications and produces little or no hemodynamic or respiratory depression. Commonly, during maintenance of general anesthesia, the inhalational gas mixture is 70% nitrous oxide and 30% oxygen, with the addition of an inhalational anesthetic or potentiation of analgesia with an opioid or a hypnotic agent. The deleterious effects of nitrous oxide are increased postoperative nausea and vomiting and, with long-term use (days), bone marrow suppression. Although there is no evidence of harmful sequelae of the use of nitrous oxide for routine anesthesia, its use has decreased because of the greater incidence of nausea and vomiting associated with it. Nitrous oxide is a potent anesthetic that is safely used in a mixture of 50% nitrous oxide and oxygen (Entonox) in obstetrics and in emergency departments to provide analgesia. Although this combination appears to be safe, it potentiates the respiratory depressive effects of opioids, and its use, in combination with any other sedative, hypnotic, or opioid agent, requires very close monitoring because it may produce general anesthesia.

Intravenous Anesthetic Agents
Anesthesia can be both induced and maintained with either intermittent boluses or continuous infusions of IV anesthetic agents. Intravenous anesthetics include barbiturates, opioids, benzodiazepines, and miscellaneous drugs, such as propofol and ketamine. Intravenous anesthetic agents can induce anesthesia more rapidly than inhalational anesthetics, with fewer complications. Vascular access is required, so unless IV access has already been obtained, inhalation induction is the preferred route. For children arriving in the operating room with vascular access, IV induction should be routine, because it rapidly takes the child from the awake state to the anesthetized state with less psychologic and cardiorespiratory compromise than occurs with inhalational induction. All IV agents affect cardiorespiratory function. The 1 exception to this may be ketamine, which, in lower doses, releases catecholamines, which maintain cardiac function and blood pressure.

Propofol
Propofol is the most commonly used IV induction agent in pediatric anesthesiology and has a rapid onset. In doses of 2-3 mg/kg, propofol induces both respiratory depression and hypotension. Propofol can sometimes burn and itch on injection. It is formulated in 10% soy emulsion with egg emulsifiers, so is contraindicated in patients with soy or egg allergy. After induction of anesthesia, propofol is also a useful agent for maintaining hypnosis and amnesia, and can be used as a sole anesthetic agent for nonpainful procedures, such as radiation therapy, MRI, and CT studies. Combined with opioids, it provides excellent, brief anesthesia for painful procedures, such as lumbar puncture and bone marrow aspiration. Propofol is a general anesthetic agent that obviates airway reflexes, respiration, and hemodynamic function; it should not be considered a “sedation agent.” Although hemodynamic stability, and even spontaneous respirations, can be maintained with cautious propofol sedation, its use for prolonged sedation over several hours to days in children younger than 12 yr is associated with hemodynamic collapse, bradycardia, metabolic acidosis, cardiac failure, rhabdomyolysis, hyperlipidemia, profound shock, and death (propofol infusion syndrome). Its use for prolonged sedation (>12 hr) in the critical care setting in children is contraindicated.

Barbiturates
The most commonly used barbiturate for IV induction is sodium thiopental, although it is now rarely used. Although loss of consciousness is rapid, barbiturates do not provide analgesia. Thiopental depresses respiration, induces apnea, and can cause hypotension in the hypovolemic patient. Induction with 3-5 mg/kg of thiopental usually produces 5-10 min of unconsciousness within seconds. After IV induction with sodium thiopental, maintenance anesthesia can be established using benzodiazepines, IV opioids, or inhalational anesthetics.

Pentobarbital is commonly used for sedation in children. It is an IV drug that induces loss of consciousness. It is also a potent respiratory depressant, particularly when used in conjunction with opioids and benzodiazepines. Pentobarbital has a very prolonged effect. It is not an analgesic agent, and painful procedures cannot be performed with pentobarbital sedation without supplemental analgesia. Pentobarbital sedation that is deep enough for anxioysis and nonpainful procedures generally results in prolonged sleep. Its potency and long duration of action make it difficult to titrate. It is not an ideal drug for sedation for short or painful procedures.

Sodium methohexital (Brevital) is another IV induction agent. It is similar to sodium thiopental and has a similar spectrum of respiratory depression.

Etomidate
Etomidate is an imidazole derivative used for the induction of anesthesia, frequently in emergency situations. Its action is not as rapid as that of propofol. The lack of cardiovascular depression has led to the use of etomidate in patients with hemodynamic compromise, cardiac disease, and septic shock. Unfortunately, by inhibition of 11β-hydroxylase, this agent depresses synthesis of both mineralocorticoids and glucocorticoids for up to 72 hr following a single induction dose. Etomidate increases mortality when used as a sedative in ICUs (for which it is now contraindicated) and when used in patients who receive merely an induction dose. Adrenal suppression by etomidate further complicates the management of the very patients with hemodynamic compromise in whom the agent has been indicated. The decision to continue use of this agent must weigh the serious risks against the short-term benefit of hemodynamic stability during anesthesia induction and sedation.

Ketamine
Ketamine rapidly induces general anesthesia that lasts for 15-30 min when given at 1-3 mg/kg IV. It has few side effects and can maintain adequate blood pressure and cardiac output. Ketamine is also effective when given intramuscularly, subcutaneously, nasally, or orally; the dose must be increased for these alternative routes. Ketamine dissociates the connections between the cortex and limbic system (dissociative anesthesia) by its inhibition of N-methyl-D-aspartate receptors, producing a unique anesthetic state. Ketamine is not only a hypnotic agent, providing obtundation and loss of consciousness, but also an analgesic agent, and can act as a sole IV agent to provide general anesthesia. With low doses of this agent, airway reflexes and spontaneous ventilation may be maintained; at higher doses, loss of airway reflexes, apnea, and respiratory depression occur. It is unwise to rely on ketamine to prevent aspiration of gastric contents during deep sedation. Intravenous ketamine is a useful general anesthetic agent for short procedures.

Ketamine produces disturbing postanesthetic dreams and hallucinations. These can occur at the time of emergence from anesthesia and for several weeks. In adults, the incidence of this effect is 30-50%; in prepubertal children, it may be 5-10%. Premedication with a benzodiazepine, such as midazolam, greatly reduces these sequelae; a benzodiazepine is routinely given to children receiving ketamine anesthesia. The other side effect of ketamine is that it is a potent secretagogue, enhancing oral and bronchial secretions. A drying agent, such as atropine or glycopyrrolate, is administered before the administration of ketamine.
A bronchial smooth muscle relaxant (bronchodilator), ketamine is a useful agent for sedating asthmatic patients and others in the ICU. Ketamine has been reported to increase intracranial pressure and therefore is not indicated in patients at risk for elevated intracranial pressure. Ketamine can increase myocardial oxygen demand and should be used cautiously in patients with impaired myocardial oxygen delivery or cardiac outflow tract obstruction.

**Opioids**

Opioids are superb analgesic agents, providing analgesia for painful procedures and postprocedural pain (see Chapter 62). Large doses of morphine (0.5-2 mg/kg), combined with nitrous oxide, provide adequate analgesia for painful procedures and surgery. Opioids suppress the CO2 response, can induce apnea, and are respiratory depressants. Morphine is often associated with hypotension and bronchospasm from histamine release; it is used with caution in children with asthma. Morphine is a long-acting agent, and an equivalent dose per kilogram gives much higher blood levels in neonates than in older children, with plasma concentrations approximating 3 times those in adults. This reason for this difference is the longer elimination half-life (14 hr) in children than in adults (2 hr). Because of the prolonged activity and hemodynamic instability induced by morphine, the fentanyl class of synthetic opioids has replaced it.

**Fentanyl** is an effective agent to provide pain relief, analgesia, and sedation for painful procedures, with a shorter duration of action and a more stable hemodynamic profile than morphine. In equal analgesic doses, all opioids are equally potent respiratory depressants. Other anesthetic agents potentiate this respiratory depression, whether they are inhalational anesthetics or IV barbiturates or benzodiazepines.

Fentanyl use at 30-50 µg/kg obtunds the hemodynamic response to surgery and provides stable operating conditions. Effective analgesia and anesthesia can be provided with IV fentanyl in a 2-3 µg/kg bolus followed by a 1-3 µg/kg/hr continuous infusion. Hemodynamic effects can be blunted and recall totally obtunded with use of a nitrous-narcotic anesthetic technique, although muscle tone may remain high and spontaneous movements can occur. Nitrous-narcotic anesthetics usually are supplemented with a nondepolarizing muscle relaxant during maintenance anesthesia. If the patient will be extubated and resume spontaneous ventilation, reversal of the muscle relaxant is necessary.

Other synthetic opioids (sufentanil, alfentanil, remifentanil) are available, but fentanyl is the most commonly used opioid. Both sufentanil and alfentanil have been used for cardiac anesthesia; their potency is different from that of fentanyl. Alfentanil appears to cause an increased incidence of muscle rigidity, convulsions, and prolonged respiratory depression compared with fentanyl, and is not used in children.

**Remifentanil** has very rapid onset and offset of action. In doses of 0.25 µg/kg/min, surgical anesthesia can be maintained with this agent. Its short half-life and rapid offset are advantageous for rapid emergence from anesthesia. Unfortunately, its rapid offset of action also leads to postprocedural and postoperative pain and requires analgesic supplementation, frequently with an opioid, which removes the advantage of anesthesia with a short-acting opioid. Remifentanil may have a role in providing rapidly deepening anesthesia for particularly painful events or rapidly inducing analgesia. It is also used intraoperatively by continuous infusion to maintain anesthesia. It is a potent respiratory depressant and provides no postprocedural analgesia, features that limit its use.

**Benzodiazepines**

Benzodiazepines induce hypnosis, anxiolysis, sedation, and amnesia, and have anticonvulsant activity. In larger doses, they cause respiratory depression and apnea; they are synergistic with opioids and barbiturates in their respiratory depressant effects. Benzodiazepines are γ-aminobutyric acid agonists.

The most commonly used benzodiazepine in pediatric anesthesia is midazolam. Short acting and water soluble, it can be injected intravenously without pain. It is a potent hypnotic—anxiolytic—anticonvulsant and is approximately 4 times more potent than diazepam. In anxiolytic doses, midazolam (0.15 mg/kg) has no effect on respiratory rate, heart rate, or blood pressure, and provides excellent preoperative sedation that is frequently accompanied by amnesia. It can be administered orally, nasally, rectally, intravenously, or intramuscularly. Use of oral midazolam at a dose of 0.5-1.0 mg/kg, mixed in sweet, flavored syrup, induces anxiolysis in approximately 90% of children. This agent has no hemodynamic, oxygenation, or respiratory depressant effects at this dose level, but when midazolam is used as a sole agent, children may frequently lose their balance and head control, may have blurred vision, and, rarely, may become dysphoric. A child sedated with midazolam should not be left unattended and is not safe walking. Most children rapidly accept an inhalational anesthetic mask after oral midazolam premedication. The widespread use of preoperative oral midazolam has decreased the practice of PPI to calm younger children.

**Dexmedetomidine**

Dexmedetomidine is an IV agent that obtunds consciousness through central α2-receptor stimulation, much like clonidine. It appears to cause no respiratory depression and produces anxiolysis, sedation, and mild analgesia. It is a sympatholytic, and its side effects include hypotension and bradycardia. Dexmedetomidine is commonly used for sedation in ICU patients as well as for procedures; it is being explored as an adjuvant for general anesthesia, especially in cardiac patients.

**Complications During Induction of Anesthesia**

The period between full wakfulness, with the child in control of airway reflexes, and general anesthesia, with total loss of control, is fraught with difficulty. During induction, laryngospasm, bronchospasm, vomiting, pulmonary aspiration of gastric contents, and subsequent aspiration pneumonitis pose a constant threat although they rarely occur. Concern about vomiting and aspiration dictates the use of preanesthetic fasting (NPO [nothing by mouth]) guidelines and indicates rapid sequence anesthetic induction.

**Laryngospasm** is the most common complication. During induction of anesthesia, especially with inhalational anesthetics, a period of excitement may occur. This period is associated with heightened airway reflexes, which can lead to coughing, gagging, laryngospasm, and bronchospasm. Laryngospasm is reflex closure of the larynx, which makes it impossible for the child to breathe or for assisted ventilation to be used. The child may make violent inspiratory efforts against a closed glottis, generating significantly negative intrathoracic pressure. This may affect cardiovascular function and cause postobstructive pulmonary edema. Laryngospasm can be prolonged, and hypoxia may ensue. Laryngospasm occurs in up to 2% of all anesthetic inductions in children younger than 9 yr and is half as common in older patients. Laryngospasm occurs twice as frequently in children with active or recent upper respiratory tract infection (URI). A history of passive smoking from environmental (parental) tobacco smoke increases the likelihood of laryngospasm 10-fold, and even more if the smoker is the child’s mother.

Laryngospasm can be relieved during induction of anesthesia by increasing the anesthetic dosage, either intravenously or through inhalation (although with the glottis closed, further administration of inhalational anesthesia is not possible). Muscle relaxation relieves laryngospasm, and in an acute situation, this situation may be an indication for succinylcholine. Constant positive airway pressure administered by someone skilled in airway management to ensure patency of the soft tissues of the oropharynx may be beneficial in alleviating laryngospasm. Laryngospasm may also occur during emergence from anesthesia, because a state of excitement is again traversed between deep anesthesia and wakfulness.

**Bronchospasm** can occur during induction, either in response to histamine release as a result of many of the anesthetic agents or as part of a hyperexcitable stage. Endotracheal intubation may also induce bronchospasm during induction. Bronchospasm during induction is particularly common in children with asthma. Bronchospasm secondary to intubation in a patient with reactive airway disease can be severe, may be associated with life-threatening hypoxemia, and may make it
impossible to ventilate the child. The use of histamine-releasing anesthetic agents has been associated with total airway obstruction, respiratory failure, and cardiac arrest. Environmental tobacco smoke is a risk factor.

Other pulmonary problems with induction of anesthesia include massive atelectasis with hypoxemia, impaired ventilation and perfusion, blunted hypoxic pulmonary vasoconstriction, and increased airway secretions with decreased bronchial function. Hypersecretion is prevented by the routine use of antialagouges, such as atropine. The newer inhalation agents are less-potent secretagouges, and the use of atropine premedication is much less common, but is probably indicated if ketamine is used.

Hemodynamic complications upon anesthesia induction include hypotension, which can be profound in hypovolemic patients; decreased myocardial function, which can be severe in patients with compromised cardiac function; and tachycardia and cardiac dysrhythmias. Inhalational anesthetics sensitize the myocardium to circulating catecholamines, and induction and excitement are associated with a hypercatecholaminergic state.

**Parental Presence During Induction of Anesthesia**

Parents may expect to be with their child during the induction of anesthesia. Removing a terrified child from the comforting arms of a parent is stressful for the child, the parent, and the caregivers. If this parental separation cannot be achieved comfortably with preoperative psychoprophylaxis and behavioral modification, including education and desensitization to the operative environment, or with pharmaco-logic aids, such as preoperative medications including benzodiazepine and barbiturates, then there may be a need to defer parent–child separation until general anesthesia is induced. Preoperative medication with oral benzodiazepine more frequently provides calm, smooth induction conditions than PPI without pharmacologic preparation. Although the use of PPI in the hands of a confident, competent anesthesia practitioner can replace the need for preoperative medication, it does not reliably predict smooth induction. PPI appears to decrease neither emergence phenomena nor the incidence of postoperative behavioral changes, and it does not appear to add an advantage for the child over that provided by preoperative sedative medication, such as with oral midazolam.

**Maintenance of Anesthesia**

Maintenance of anesthesia is the period between induction and emergence. The child should be asleep, unaware of pain, unresponsive with either motion or hemodynamic responses to painful stimuli, and homeostatically supported. The child is comatose, without airway-protective reflexes and with suppression or absence of respiration, and has received drugs that suppress hemodynamic adaptive responses. The child is also exposed to surgical trauma, and there may be blood loss and significant fluid shifts (third spacing), decreased intravascular volume, and hypothermia.

Anesthesia is usually maintained with or without nitrous oxide, an inhalational anesthetic such as isoflurane or sevoflurane, and an opioid for intraoperative analgesia, potentiation and deepening of anesthesia, and postoperative analgesia. A benzodiazepine is added either during premedication or intraoperatively to supplement hypnosis and amnesia. A nondepolarizing muscle relaxant (vecuronium or rocuronium) completes the pharmacologic maintenance of anesthesia. Agents can be given by continuous inhalational anesthesia or by continuous or bolus IV infusion.

During maintenance, the child may breathe spontaneously through an anesthetic mask or endotracheal tube or may be mechanically ventilated. All general anesthetic agents decrease end-expiratory lung volume, which is generally lower than functional residual capacity, with increases in pulmonary closing capacity and intrapulmonary shunt. Hypoxia would occur without supplemental oxygenation. These effects are compounded by respiratory depressant effects and the depressed CO₂ response curve. Therefore, it is generally considered that use of anesthetics for longer than 1 hr requires endotracheal intubation and positive-pressure ventilation. For long procedures, spontaneous breathing through a mask is possible; in smaller children, in whom the surgical field and the airway may be close together, the need to maintain a patent airway necessitates endotracheal intubation.

**Muscle relaxation** to facilitate endotracheal intubation was once accomplished with succinylcholine. This agent has a high-risk profile, however, and is associated with postoperative pain (muscle spasms); hyperkalemia; elevated intracranial, intraocular, and intragastric pressures; malignant hyperthermia; and myoglobinuria and renal damage. Succinylcholine is now rarely used, except to provide rapid relief of laryngospasm. Intubation of the airway is facilitated with a nondepolarizing, short-acting muscle relaxant. Rocuronium is the drug most commonly used for intubation. After intubation of the airway, the decision must be made whether to maintain muscle relaxation to facilitate surgery or to allow the child to resume spontaneous respiration. Prolonged use of a nondepolarizing muscle relaxant is common practice but may contribute to postoperative respiratory compromise if it is not fully reversed with appropriate agents.

**Reversal of neuromuscular blockade** is standard anesthetic practice. Effects of nondepolarizing muscle relaxants are reversed by increasing the concentration of acetylcholine with neostigmine (ace-tylcholine esterase inhibitor) and either atropine or glycopyrrolate to prevent the vagal effects. With the virtual abandonment of succinylcholine, only nondepolarizing muscle relaxants are routinely used for intubation. The termination of their action depends on metabolism and elution away from the neuromuscular junction. This process, even for the shortest-acting muscle relaxants (rocuronium), can take several minutes. An intubating dose of rocuronium to rapidly induce paralysis in emergency situations may not spontaneously reverse for 20 min or longer (compared with ~3 min for succinylcholine). If the airway cannot be secured, disaster may follow in the child who is unable to breathe spontaneously and in whom blockade cannot be reversed.

**Thermoregulation** is critical during anesthesia. The absence of movement and the inhibition of shivering lead to difficulty in thermogenesis. All the contributors to heat loss—convection, radiation, evaporation, and conduction—occur during anesthesia. Humidification and warming of inspired air are required. Additional warming devices are commonly used, such as rewarmin blankets. General anesthetic increase the interthreshold range (the minimal temperature change that will lead to sympathetic response, generally 0.3°C [0.5°F]). Although temperature sensing may remain normal, an autonomic response to hypothermia is not triggered. Anesthetic agents cause vasoparesis, which further impedes thermoregulation and increases heat loss. In newborns, inhalational anesthetics inhibit noshivering thermogenesis from brown fat, putting them at higher risk for hypothermia.

**Fluid Maintenance During Surgery and Anesthesia**

Patients who are unconscious and immobile have lost venous pump mechanisms and have peripheral venous pooling. Anesthetic agents cause vasodilation, and anesthetized patients have relative hypovolemia. Intravascular volume expansion is frequently required after the induction of anesthesia to maintain adequate perfusion, tissue oxygenation, urine output, and blood pressure. Volume expansion is most commonly provided by isotonic salt-containing solutions (normal saline, lactated Ringer solution). Autonomic responses may be increased as part of the surgical stress response, with vasoconstriction and intravascular volume contraction caused by diuresis, intravascular volume loss from hemorrhage, evaporation (insensible loss, increased during surgery), and third space (interstitial space) fluid losses resulting from the inflammatory response. Abnormalities in the distribution of renal blood flow and secretion of antidiuretic hormone further complicate the regulation of intravascular volume.

The concern about **hypoglycemia** as a result of preoperative fasting led to the recommendation that infants and small children receive
isotonic solutions with 5% glucose. The occurrence of hyperglycemia and potential neurologic injury during cardiopulmonary bypass, or during neurosurgery and other situations in which central nervous system injury can occur, however, along with the recognition that hypoglycemia is rare in nonneonates, has called into question the routine use of glucose-containing solutions. In neonates, glucose monitoring during and after anesthesia is indicated. In older children with normal nutritional status, isotonic salt solutions without additional glucose are adequate. In children who are receiving parenteral alimentation with a solution containing a high glucose concentration (>10%), continuation of the glucose concentration should be ensured to avoid rebound hypoglycemia, which would occur if the high-glucose solution was stopped.

Intraoperative fluid maintenance includes (1) current maintenance fluids and replacement of usual deficits during the NPO period; (2) replacement of third space losses; and (3) replacement of extraordinary losses (hemorrhage). Infants should receive glucose-containing isotonic fluids, such as 5% dextrose in water with either 0.25 normal saline or isotonic crystalloid solutions. Table 61-6 is a guideline for determining fluid deficits and maintenance requirements in the operating room. Fluid deficits should be replaced over the 1st 2 or 3 hr of intraoperative management. Deficits are generally calculated as the number of hours of NPO status multiplied by the hourly maintenance rate for the child. Half of this deficit is replaced during the 1st hr and half during each of the subsequent 2 hr. If hypotension or tachycardia occurs or persists in the early stages of anesthesia, more rapid replacement of the fluid deficit is indicated. The deficit is replaced with isotonic crystalloid solutions.

Third space losses are replaced with isotonic salt solutions. For large operations, such as abdominal or thoracic procedures, during which there may be a large amount of evaporative loss as well as a significant amount of third space loss, 8-10 mL/kg per hr of surgery is generally given as IV fluid replacement. For smaller operations, such as herniorrhaphy, pylonotomy, and minor procedures, fluid replacement at 3-5 mL/kg/hr is indicated for third space losses. Even when surgery involves the extremities and third space losses are minor, it is wise to give an additional 1-2 mL/kg/hr to replace them.

A crystalloid solution is indicated for blood loss, at 3 mL per mL of blood lost. This formula could be reduced somewhat if blood is replaced on an mL-per-ML basis with packed red blood cells or whole blood equivalent. The use of albumin or other suitable colloid, such as fresh-frozen plasma in neonatal surgery, also decreases the amount of crystalloid replacement needed for blood loss. During maintenance anesthesia, if large-volume transfusions are required, warming the blood and crystalloid solutions avoids hypothermia. With major surgery and the resultant systemic inflammatory response syndrome, capillary integrity is lost and third space losses are common. Failure to replace this third space loss and restore intravascular volume leads to hypotension, shock, acidemia, and renal failure, and further stimulates the systemic inflammatory response syndrome.

### RECOVERY FROM ANESTHESIA

Recovery from anesthesia includes emergence and postoperative recovery from surgery and anesthetics. Emergence describes the time and the physiologic response to decreasing depth of anesthesia during return to consciousness. During emergence, patients experience decreased anesthetic effect, increased stress responses, physiologic and psychologic responses to painful stimuli, excitement, and anxiety. Conscious realization of pain may lead to physiologic responses during emergence. Normal physiologic functions, such as spontaneous ventilation, resume and hemodynamic function improves. After routine elective procedures, the child should be fully conscious before leaving the operating room, with intact airway reflexes, the ability to follow simple commands, the effects of muscle relaxants reversed, and airway patency maintained. If the child is going to the ICU, or if for surgical reasons the decision is made to leave the child intubated, analgesia and sedation should be maintained, along with mechanical ventilation, in the postoperative period. Ideally, emergence should be as brief as possible, with maintenance of analgesia and anxiety and restoration of cardiorespiratory function. Inhalational anesthetic agents leave the system rapidly during ventilation, and muscle relaxants can be reversed; however, the effects of opioids, benzodiazepines, and IV hypnotic agents may be prolonged.

During emergence, the decision must be made whether to reverse the effects of muscle relaxants. The effects of long-acting, nondepolarizing muscle relaxants (vecuronium and pancuronium) are invariably reversed. If the child appears to be weak or to have respiratory depression in the postoperative phase, prolonged neuromuscular blockade should be considered.

### POSTANESTHESIA CARE UNIT

In the postanesthesia care unit (PACU), the child is observed until there is adequate recovery from anesthesia and sedation. Parents should be permitted to comfort their children in the PACU. Achievement of spontaneous breathing, adequate arterial saturation (>95%), and hemodynamic stability are key recovery end points. The child should be arousable, responsive, and oriented before discharge from the PACU. The amount of time spent in the PACU depends on whether the child is being discharged to an inpatient nursing unit, to an ICU, to a postrecovery area, or directly home. Discharge from the PACU depends on the child’s overall functional status—not merely the physiologic end points, but also the behavioral end points as well as the adequate provision of analgesia and control of postoperative nausea and vomiting. There are several scoring systems (Table 61-7) for determining whether a child is ready to be discharged from the PACU.

### Complications in the Postanesthesia Care Unit

#### Respiratory Depression

Prolonged emergence from anesthesia and respiratory depression can be caused by opioids or inadequate antagonism of neuromuscular blocking agents. Pain can cause significant hypoventilation, especially after thoracic or abdominal surgery. Delayed emergence from anesthesia can occur as a result of retention of inhaled anesthetic agents worsened by hypoventilation. Hypothermia, especially in neonates, delays metabolism and excretion of anesthetics and also aggravates neuromuscular blockade. If respiratory depression is profound, then maintenance of the airway may require an oral airway. If the depression is severe, endotracheal intubation and mechanical ventilation are indicated.

Only in rare cases, in which opioid suppression is suspected, is reversal of the effects of opioid with naloxone indicated. Opioid reversal with naloxone reverses not only the respiratory depression but also the analgesia. A somnolent child with respiratory depression may become excited, agitated in severe pain, uncontrollable, and/or hypertensive after naloxone. Opioid reversal necessitates bedside attention by the physician to monitor the child’s behavioral, hemodynamic, and respiratory status. Naloxone is shorter-acting than most opioid analgesics.

**Atelectasis** is another respiratory complication occurring in the 1st 48 hr after anesthesia. Although atelectasis suggests an inhaled foreign body, it is most likely caused by secretions and decreased respiratory effort secondary to pain. Microatelectasis may lead to postoperative infections. Aspiration pneumonia is another postoperative complication.

**Postoperative stridor** occurs in up to 2% of all pediatric patients. The use of uncuffed, atrumatic, nonirritant endotracheal tubes has decreased the incidence of airway trauma. The use of appropriately sized endotracheal tubes and assurance of an air leak <30 cm H₂O
pressure further decreases the risk of airway trauma. A history of stridor increases the likelihood of postoperative complications. Stridor may be severe enough after extubation to require reintubation. Retractions and respiratory distress in the postoperative period should suggest this complication, and stridor or wheezing should confirm the diagnosis. Racemic epinephrine aerosols are effective therapy; their use requires prolonged observation because of the potential for recurrence of the airway obstruction. Stridor in infants suggests the need for overnight observation.

Hemodynamic instability is much less common in the PACU. Volume expansion may be required to maintain adequate blood pressure, peripheral perfusion, and urine output. Requirement for excessive volume replacement (>30 mL/kg) to maintain blood pressure, perfusion, and urine output in the postoperative period is an indication of shock and occult bleeding, and it necessitates surgical consultation.

**Emergence delirium** is noted in <3% of children and is more common in those 3–9 yr old. In the immediate hour after surgery, children may become extremely restless, combative, and disoriented, and may be screaming, inconsolably crying, or poorly communicative. These children pose a danger to themselves. This phenomenon is more common when barbiturates are used as part of premedication or induction and inhalational anesthetics or ketamine forms part of the maintenance anesthetic. Although disorientation is common in the postanesthetic stage, erratic, delirious behavior requires attention, with gentle restraint, a quiet environment, and comforting. Potential postoperative complications, such as hypoglycemia and hypoxemia, should be ruled out. Occasionally, it is necessary to sedate the child with benzodiazepines, although these agents prolong postanesthesia recovery time and when they wear off, emergence delirium may recur.

### Awareness During Anesthesia
A primary goal of anesthesiology is obtunding consciousness to ablate awareness during procedures and recall afterward. In adults, certain anesthetic techniques are associated with an unacceptably high incidence of recall during anesthesia. Awareness and recall of events during a surgical procedure can be unpleasant and terrifying; the long-term sequelae of such recall in children are unknown. Continuous monitoring of cerebral electroencephalographic function by monitoring of the bispectral index has been recommended. Unfortunately, data in children do not confirm the efficacy of bispectral index monitoring as a means of determining anesthetic depth, and this fact, combined with the absence of meaningful data on intraoperative awareness and recall in infants and children, does not currently support the routine use of bispectral index monitoring.

### Postoperative Nausea and Vomiting
After general anesthesia, 40–50% of children may experience nausea and vomiting. More than 80% of all high-risk children receiving inhalational anesthesia experience postoperative nausea and vomiting (PONV). It may occur in the immediate postoperative period, within the 1st 1–2 hr, or several hours after surgery and anesthesia. The etiology may be related to the stress and trauma of surgery combined with the emetic effects of anesthetic agents. Pain is an important cause of nausea and vomiting. Opioid analogs also induce nausea and vomiting. Preoperative fasting does not decrease the incidence of nausea and vomiting. Indeed, hydration and glucose supplementation appear to be important factors in decreasing PONV. The use of analgesics other than opioids (acetaminophen, ketorolac) and regional or local anesthesia is associated with decreased PONV.

This complication prolongs recovery room times, requires significant nursing attention, and increases the use of potent antiemetic agents (ondansetron, other serotonin antagonists). Ondansetron is very efficacious as a prophylactic and in the treatment of PONV. Ondansetron and other serotonin antagonists are recommended for high-risk patients (strabismus surgery) or for actual treatment of PONV. They are contraindicated in children taking serotonin reuptake inhibitors for migraine headaches. Metoclopramide is useful prophylactically. Droperidol (which has an FDA-required black box label warning) must be used with caution because of the rare occurrence of prolonged QT interval and ventricular arrhythmias associated with its use.

### Thermoregulation and Malignant Hyperthermia
For patients in the PACU, thermoregulation remains abnormal for several hours. Shivering is common in the postoperative state, and a feeling of extreme cold is common. Warm blankets are very comforting and seem to decrease shivering. **Hyperthermia**, especially in neonates, leads to hypotension, bradycardia, acidosis, apnea, and prolongation of the effect of opioids and neuromuscular blocking agents. Although hyperthermia has deleterious effects, rewarming must be done cautiously to avoid burning and cutaneous hyperthermia. **Hyperthermia**, with temperatures in excess of 39°C (102.2°F), is of concern in the postoperative period. If it occurs within hours of the use of an inhalational anesthetic, especially if succinylcholine was used, malignant hyperthermia must be suspected.

**Malignant hyperthermia** is an acute hypermetabolic syndrome that is triggered by inhalational anesthetic agents and succinylcholine. It resembles neuroleptic malignant syndrome. The onset of malignant hyperthermia may be acute, and its course may be fulminating and rapidly fatal. This condition, albeit rare (approximately 1 in 60,000 pediatric patients given anesthesia) is a constant concern. The disease is familial, and a family history of death or a febrile reaction during anesthesia should alert the anesthesiologist to its potential. Its clinical course is characterized by rapid onset of fever, acidosis, hypercarbia, and increased expired CO₂. High fever (38.5–46.0°C [101.3–114.8°F]),
rising 1°C [1.8°F] every 5 min), muscle rigidity, metabolic acidosis, and hemodynamic collapse can occur. Death ensues from shock and cardiac dysrhythmias with ventricular fibrillation that is unresponsive to treatment. The mortality rate for malignant hyperthermia was once >70%. Aggressive therapy, including discontinuation of all inhalational anesthetic administration, correction of the metabolic acidosis, and treatment with the muscle relaxant sodium dantrolene, has reduced the mortality rate to <5%. Dantrolene and a kit containing supplies necessary to treat malignant hyperthermia should be present at every site where pediatric anesthesia is provided.

Malignant hyperthermia is probably genetically heterogeneous, with more than 10 genes contributing to susceptibility. Genetic mutations in the ryanodine receptor (the calcium channel of the sarcoplasmic reticulum) have been reported in 20-40% of humans with malignant hyperthermia. Certain myopathies are associated with the risk of malignant hyperthermia; these include Duchenne muscular dystrophy, Noonan phenotype, and, in children with a history of pttosis, squint, scoliosis, and muscle cramping. It is wise to avoid the use of succinylcholine in children with myopathies.

Malignant hyperthermia appears to occur from a massive triggering of excitation contraction coupling, sarcocelmal calcium release, and propagation of contraction by a complex biochemical process. The prolonged ischemic contraction leads to myolysis, with release of myoglobin, very high serum creatine phosphokinase levels, and renal failure secondary to myoglobinuria. Malignant hyperthermia generally occurs within the 1st 2 hr of anesthesia, but (rarely) can occur up to 24 hr later.

Certain phenomena are clues to the risk of malignant hyperthermia. The occurrence of masseter spasm during induction, with rigid clenching of the masseter muscles and an inability to open the mouth, may presage full-blown disease. Acute myoglobinuria associated with a malignant hyperthermia triggering agent is another clue. The child may not be hypermetabolic or febrile, but may have dark urine and high serum creatine phosphokinase levels, with the risk of myoglobin-induced renal tubular damage. The finding of dark urine after administration of an anesthetic requires investigation for malignant hyperthermia. An elevated creatine phosphokinase value and hemopositive urine in the absence of red blood cells in the urine indicate a need for renal protection with mannitol and alkaline diuresis.

Rapid therapy is essential. All known triggering agents must be stopped. Intravenous administration of dantrolene sodium (2.5 mg/kg IV as an initial dose) is begun as soon as possible. The need for repeated doses is indicated by the persistence of muscle rigidity, acidosis, and tachycardia, up to a maximum dose of 10 mg/kg. Once the symptoms are controlled, the patient should be observed for at least 24 hr after the laboratory values have returned to normal, because relapse can occur.

Prevention of malignant hyperthermia in susceptible patients requires the avoidance of triggering agents, which include inhalational anesthetics. Most anesthesiology departments are capable of delivering general anesthetics using anesthesia machines from which all traces of anesthetic vapors have been removed. Intravenous anesthesia and a nitrous-oxide technique are safe. Dantrolene prophylaxis is not recommended because the disease is rapidly treatable and because the drug causes respiratory depression and muscle weakness. For a child in whom malignant hyperthermia is suspected, the malignant hyperthermia hotline, 1-800-MHHYPER (1-800-644-9737), should be used to notify the Malignant Hyperthermia Association of the United States (MHAUS). The Malignant Hyperthermia Association registers susceptible patients and provides diagnostic and therapeutic information. Preanesthesia susceptibility testing includes genetic analysis of the ryanodine receptor gene, muscle biopsies, in vitro contraction studies, and, possibly, measurement of muscle CO2 production in response to intramuscular caffeine.

Postoperative Apnea
Apnea within the 1st 48 hr after surgery and anesthesia in premature infants is common; both central apnea and obstructive apnea (mixed apnea) may occur. The use of respiratory depressants may impair respiratory control in neonates. Apnea is also a recognized stress response in neonates, and inadequate anesthesia is associated with increased apnea and respiratory complications.

The risk of postoperative apnea in premature neonates is inversely proportional to postconceptual age at the time of surgery. This risk is minimal by the time premature infants have reached the postconceptual age of 60 wk. Apnea is most common within the 1st 12 hr after surgery; postanesthetic apnea has been reported in premature infants up to 48 hr later. The incidence of apnea in full-term infants is debatable and has not been clearly demonstrated. It is generally agreed that general anesthesia should be avoided, except for emergency surgery, in full-term children younger than 44 wk postconceptual age. If surgery is required within the 1st mo of life, overnight observation and monitoring are indicated. Theophyllines decrease the incidence of postoperative apnea; they do not ablate it and therefore are not routinely used. The safest course is to monitor premature infants younger than 60 wk postconceptual age and full-term infants younger than 1 mo for at least 24 hr after anesthesia.

PREANESTHETIC EVALUATION
Most previously healthy children require minimal preoperative assessment. The American Society of Anesthesiologists (ASA) classification system for anesthetic care is the American Society of Anesthesiologists Physical Status classification (Table 61-8).

For American Society of Anesthesiologists Physical Status 1 patients, a brief history, notation of medical allergies, and a physical examination focusing on the airway, lungs, and cardiac function are sufficient. For all children who are being assessed for anesthesia risk, a family history should be obtained, for reactions to anesthetics, for drug allergies, and for sudden intraoperative death or hyperthermia after surgery, which may indicate a risk of malignant hyperthermia. In previously anesthetized children, questions should be asked regarding intraoperative anesthetic complications. The history should focus on determining whether the child is at risk for anesthetic or surgical stress as well as cardiorespiratory disease and airway compromise.

Recent URIs should be noted. A URI is an upper respiratory illness associated with fever, mucopurulent green or yellow nasal discharge, productive cough, injected sclerae, and increased mucous secretions. Clear rhinorrhea is generally not a concern. URIs can increase airway reactivity for up to 6 wk in both normal children and children with a history of reactive airway disease. URIs can also increase the risk of laryngospasm and bronchospasm, reduce mucociliary clearance, and raise the risk of intraoperative atelectasis and hypoxemia. It is generally recommended to avoid general anesthesia for elective procedures for 4-6 wk after a URI. In patients with chronic sinusitis and nasal polyps, infection should be thoroughly treated before elective anesthesia.

Acute, fatal bronchospasm can occur during induction of anesthesia and endotracheal intubation for routine, minor surgery in children with asthma. Those children at particular risk for anesthetic complications with asthma are those who were (1) admitted to the hospital within the previous year for their asthma, (2) seen in an emergency department in the last 6 mo, (3) admitted to an ICU, or (4) treated with

Airway Evaluation

Because the induction of anesthesia is associated with loss of spontaneous ventilation and airway reflexes, predicting the inability to bag-and-mask ventilate or endotracheally intubate a child before anesthesia is critical. The anesthesiologist must be told if the child has congenital anomalies that affect the airway (Table 61-9). Such anomalies include micrognathia syndromes, macrognathia syndromes, and some thoracic anomalies. Congenital anomalies associated with airway compromise should be diagnosed preoperatively. Conditions that impair mouth opening (temporomandibular joint disease) should be noted. A history of wheezing or stridor may indicate postoperative airway complications and difficult intraoperative airway management.

Mediastinal Masses

Children with anterior mediastinal masses, such as lymphomas and primary mediastinal tumors, are at serious risk for airway compromise, cardiac tamponade, and vascular obstruction. Induction of general anesthesia and even mild sedation can lead rapidly to total loss of the airway, with inability to ventilate the child and cardiovascular collapse. These patients often present in a semiemergency fashion, with the need for both a tissue diagnosis of the mass before treatment is initiated and a surgically placed central venous line.

Significant compression of vital structures can occur with seemingly mild symptoms. Tachypnea, orthopnea, wheezing, and sleep disturbances or avoidance of prone or supine positions are significant indicators of serious risk. Pericardial tamponade or superior vena cava syndromes are more concerning findings. A CT scan showing >50% compression of the airway at the carina is an indication to prohibit general anesthesia and provide only mild sedation. Echocardiographic or CT evidence of pericardial tamponade, right ventricular compression, or compression of the pulmonary artery suggests severe risk.

Biopsy with the child under local anesthesia may be indicated. If anesthesia is required, cardiopulmonary bypass should be considered, in case it becomes impossible to ventilate the child during surgery. In high-risk children, consideration should be given to initiating treatment with steroids, radiation therapy, and chemotherapy before obtaining a tissue diagnosis.

Down Syndrome

Children with Down syndrome are occasionally behaviorally difficult and are especially fearful of medical caregivers (see Chapter 81). Their cardiac anomalies, macrognathia, and upper airway obstruction can be challenging. Children with Down syndrome have atlantoaxial instability due to odontoid hypoplasia and joint laxity (see Chapter 680.3). In younger children, extension of the neck, routinely used to maintain and intubate the airway, may lead to cervical dislocation and spinal cord trauma. Some anesthesiologists recommend extension and flexion lateral neck films to detect instability before anesthesia. In children with Down syndrome, it is wise to exercise caution in stabilizing the cervical spine and also to avoid cervical flexion and extension.

Cardiovascular System

Because of the depressant effects of anesthetics and the increased metabolic demands of surgery, any compromise of myocardial function should be clearly delineated preoperatively. A preoperative electrocardiogram, an echocardiogram, and a cardiology consultation are indicated for children with a history of heart disease. An intracardiac shunt will affect oxygenation status intraoperatively. Because of the significant effect on the oxygen supply-and-demand relationship caused by general anesthesia and surgical stress, obstructive lesions, such as a valvular stenosis, must also be clearly defined. A history of cardiac dysrhythmias should be clearly understood, because inhalational anesthetics are dysrhythmogenic.

In neonates, ductus arteriosus, myocardial compromise, pulmonary edema, or congenital heart disease can significantly complicate oxygen delivery during anesthesia. Accurate diagnosis of cardiac murmurs in neonates is essential. Any preoperative cardiovascular compromise will be worsened intraoperatively and can catastrophically complicate the perioperative course.

Anemia should be diagnosed and corrected preoperatively if possible. A hematocrit value >30% is generally acceptable for routine elective anesthesia. If there are reasons to expect significant blood loss or prolonged convalescence, anemia should be corrected preoperatively. In the emergency setting, transfusion may be required. Although lower hematocrit values can be tolerated in unstressed children, the significant threat to oxygen delivery posed by anesthesia and surgery, especially if blood loss is expected, requires maintenance of an adequate hemoglobin concentration perioperatively.

Evidence of coagulopathy should be sought. Easy bruising, the use of aspirin, and familial bleeding disorders should be discussed. Intraoperative hemorrhagic bleeding can be difficult to control; massive perioperative blood transfusions have significant risk of morbidity and mortality. Preoperative correction of coagulopathic disorders is indicated. In neonates, assurance of vitamin K prophylaxis and adequate coagulation status is critical before any significant surgery. In neonates and critically ill children, adequacy of platelet count and, where indicated, coagulation factors, prothrombin time, and partial thromboplastin time should be assured.

Neurobehavioral Considerations

Seizures, significant neurologic impairment, altered level of consciousness, respiratory airway compromise secondary to neurologic disease, and neuromuscular disease should be sought and evaluated. Anticonvulsant drug metabolism is often altered perioperatively, and this change may affect anticonvulsant drug levels. Anticonvulsants may also complicate anesthetic management. Maintenance of appropriate anticonvulsant therapy postoperatively is important to avoid new seizures. Cerebrospinal fluid secretion is increased during surgery and general anesthesia. This fact is significant in patients in whom elevated intracranial pressure is suspected and in children with ventriculoperitoneal
shunts. In infants or older children with ventriculoperitoneal shunts, shunt patency and function should be assured before surgery.

Illness and the need for surgery or painful medical procedures are psychologically traumatic events for children and their families. Children are also remarkably adept at sensing stressful signals from their parents and caregivers. Many children who require anesthesia may have significant levels of fear and anxiety. Most children undergoing surgery have new-onset negative behavioral changes in the postoperative period, such as maladaptive behavioral responses that include generalized anxiety, enuresis, enhanced separation anxiety, temper tantrums, nighttime crying, and fear of strangers, doctors, and hospitals. Approximately 20% show these negative behavioral adaptations for 6 mo after surgery. Sleep quality is also altered postoperatively, resulting in further behavioral compromise.

The risk factors for postoperative behavioral changes include preoperative or induction anxiety and behaviors indicating extreme stress, as well as emergence excitation. The type of surgery may be important, with tonsillectomy and genitourinary surgery having a high incidence of postoperative behavioral changes, whereas simple procedures (tympanostomy tubes) seem to be associated with fewer changes. Another risk factor is recurrent procedures, such as anesthesia for laser surgery, strabismus surgery, or repeated eye examinations, which lead to difficult behavioral changes and have a significant effect on family dynamics.

Preoperative psychologic preparation programs decrease the incidence of postoperative behavioral changes, which last for up to 1 mo. PPI does not improve postoperative behavior. Oral midazolam (0.5 mg/ kg) may decrease negative behavioral changes after surgery. Midazolam has the benefit of providing not only rapid-onset anxiolysis in 10-20 min but also very effective and rapid (10 min) amnesia.

Preoperative Preparation
The child should be in the best possible nutritional state, and nutritional supplementation, even hyperalimentation in chronically ill children, may be worthwhile.

Preoperative Fasting
Aspiration of gastric contents is a perioperative disaster and, if superimposed on lung disease, may be rapidly fatal. Aspiration may lead to laryngospasm and bronchospasm, with hypoxemia and hypoxic ischemic encephalopathy. It may also produce intraoperative atelectasis and postoperative pneumonia. It is vital to ensure that the stomach is as empty as possible before the induction of anesthesia. Acid aspiration is less likely with an empty stomach. Table 61-10 lists preoperative fasting (NPO status) guidelines.

*These are general guidelines and may differ among hospitals.

The Full Stomach
Because of the serious complications of aspiration of gastric contents, it is desirable to secure the airway as rapidly as possible after obtundation in patients at risk for having a full stomach. Gastric emptying may be delayed for up to 96 hr after an acute episode of trauma or surgical illness. Under these circumstances, induction of general anesthesia and endotracheal intubation are performed in a rapid sequence (rapid sequence induction; see Chapter 67).

The risks of rapid sequence induction include the possibility that if the airway cannot be intubated, the child is paralyzed without a protected airway and ventilation may be hazardous or impossible. Rapid sequence induction should be performed by those who can definitely achieve endotracheal intubation quickly. It should be avoided in patients with a history of failed oral endotracheal intubation or with any of the many syndromes (micrognathia) associated with difficult intubation. Under these circumstances, bronchoscopic awake intubation may be indicated.

Before rapid sequence anesthesia induction, the child should be preoxygenated by breathing 100% oxygen for 2 min to give an extra margin of safety if intubation is difficult. The child should not receive assisted ventilation either before or after the administration of drugs because this may lead to increased gastric air and actually increase the likelihood of vomiting, regurgitation, and aspiration.

One common regimen for rapid sequence induction includes the administration of 1.5-3 mg/kg of propofol concurrently with either 0.9-1.2 mg/kg of rocuronium or 1.5 mg/kg of vecuronium. Immediately after the administration of sedation and muscle relaxants, the Sellick maneuver (cricoid pressure) should be performed by applying firm pressure in a posterior direction against the cricoid cartilage. This displaces the cricoid cartilage into the esophagus, forming an artificial sphincter to prevent reflux of the gastroesophageal contents. Cricoid pressure should be maintained until correct placement of the endotracheal tube is verified by direct visualization, fogging of the tube, and, in all circumstances, positive end-tidal CO2.

**POSTOPERATIVE PAIN MANAGEMENT**
Continuation of analgesia and anxiolysis should follow surgery or painful procedures (see Chapter 62). Complete freedom from pain is not possible. Preoperative education about the surgery and a pain management plan, development of skills designed to decrease anticipatory anxiety, and active participation in treatment planning can be helpful for some children and families. Adjunctive therapy, such as virtual reality, hypnosis, pet therapy, and play therapy, also can decrease the need for potent analgesics postoperatively.

The combination of opioid and nonopioid analgesic agents and an understanding of the benefits and risks provide the foundation of pain management. A judicious combination of nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, intravenous acetaminophen, opioids, and regional analgesia has a role in postoperative pain management. Repeated evaluation is as important as the modality of pain management. Continuous and repetitive small doses of analgesia around the clock are more effective at reducing pain than occasional prn dosing intervals.

Patient-controlled analgesia (PCA), nurse-controlled analgesia, and parent-controlled analgesia are all used postoperatively (see Chapter 62). PCA provides continuous pain treatment and self-medication (vs intermittent or prn pain control) as well as control and comfort in an otherwise personally uncontrolled circumstance. PCA provides both a background low-dose infusion rate of a continuous opioid and the opportunity to supplement analgesia with bolus doses as needed. The practitioner can determine the continuous infusion rate, the bolus dose, the lockout interval, and the number of boluses per unit time that the patient may receive. PCA relies on the theory that patients cannot or will not overdose themselves because somnolence will decrease repeated self-administration. In young children, the use of the pain button (for pain relief) may be more difficult to ensure; children as young as 5 yr old have been able to use PCA successfully. In older children and adolescents, PCA should be a standard modality of postoperative pain management.
Regional Anesthesia

Regional anesthesia is the use of anesthetics to block the conduction of afferent neural impulses to the central nervous system. These can be local analgesic techniques, peripheral nerve blocks, nerve plexus blocks, or epidural and subarachnoid (spinal) nerve blocks. They may be administered either through a single injection (single shot) or through continuous infusion, as is common with epidural and occasionally subarachnoid blocks. They may be used for intraoperative anesthesia and postoperative analgesia, and they have the potential to decrease intraoperative analgesia and anesthetic use, as well as to provide postoperative pain management. Increased use of regional indwelling catheters to deliver continuous analgesia has shortened recovery times and hospital stays in children.

Analgesia at the site of need, without central cardiorespiratory depressant effects, can be valuable. Local anesthesia, with injection of lidocaine or bupivacaine into the affected area, can provide procedural analgesia that lasts for several hours. Infiltration of the wound site and the edges of an incision decreases postoperative pain in the initial hours after surgery. This can be performed by the surgeon at the conclusion of surgery and may supplement postoperative analgesia.

Epidural analgesia is common in pediatric practice. The epidural space lies between the dura and the pia and arachnoid membranes, an area through which all nerve roots pass. Bathing these nerve roots in local anesthetics inhibits conduction of pain impulses centrally. A single dose of epidural anesthetic may provide hours of pain relief, and a continuous infusion may provide effective pain relief for hours to days. The epidural injection of opioids can provide analgesia for 12-24 hr and is a potential supplement to postoperative analgesia.

A lumbar epidural injection is placed in the lumbar area to provide analgesia for labor and for surgery below the thorax. Caudal epidural analgesia is placed through the sacral hiatus, inferior to the distal end of the spinal cord. This is the site most commonly used for regional anesthesia and analgesia in children and is efficacious for the provision of pelvic and lower limb anesthesia as well as beneficial in orthopedic and urologic surgery. A continuous infusion of bupivacaine is the most common means of providing postoperative epidural pain relief; it may be mixed with an opioid (fentanyl or preservative-free morphine). It is also possible to provide epidural PCA with a continuous infusion pump and the ability of the patient to self-medicate with bolus prn dosing. Epidural analgesia can also provide pain relief in patients with chronic pain or pain caused by advanced malignant conditions.

The most serious complications of neuraxial anesthesia include respiratory depression, paralyzation of respiratory muscles, and, in extreme cases, brainstem analgesia and depression. The most common complications of neuraxial analgesia include mild discomfort; a paresthesia-like feeling of numbness and tingling; pruritus, which, if opioids are used, can be quite distressing; and occasional nausea and vomiting. Infection and epidural hematoma are extremely rare. Neuraxial opioids, especially when administered intrathecally, can cause respiratory depression; their use requires postoperative monitoring. The use of neuraxial opioids often requires treatment with antipruritic as well as antiemetic drugs.

61.1 Sedation and Procedural Pain

Randall C. Wetzel

The same drugs that induce general anesthesia are often used to provide sedation (see Table 61-5). Sedation care requires a presedation evaluation, intraprocedural monitoring, and postsedation recovery, analogous to the provision of anesthesia. Sedation is on the continuum between wakefulness and general anesthesia (see Table 61-4). The term conscious sedation refers to a condition in which a patient is sleepy, comfortable, and cooperative but maintains airway-protective and ventilatory reflexes. Unfortunately, for most children, this level of sedation provides little or no analgesia, and both psychologic and physiologic responses to painful stimuli persist. Sedation that is sufficient to obtund painful responses is most likely deep sedation. Deep sedation is a state of unarousability to voice and is accompanied by suppression of reflex responses. Management of sedated children requires vigilance and knowledge to ensure their safety and is governed by the same guidelines as anesthesia care (Table 61-11). A dose of sedative medication that causes minimal sedation in one subject may produce complete unconsciousness and apnea in another. Careful attention to guidelines for appropriate monitoring and management of sedation in children is imperative. For threatening and nonpainful procedures, anxiolysis or light sedation is frequently sufficient. For painful procedures (e.g., bone marrow aspiration, insertion of percutaneous IV catheter lines, lumbar punctures), the combination of sedation with analgesia that is required in children produces deep sedation.

Many specialists provide sedation and anesthesia care for children. The use of anesthetic agents is not limited to anesthesiologists, but a hospital’s department of anesthesiology provides expertise in developing and managing systems of anesthesia care, including sedation. With the widespread use of the deceptively safe general anesthetic agent propofol to provide sedation, hospitals, pediatricians, and other care providers must ensure that credentialing, oversight, quality assurance, and protocols for administration of anesthetic agents provide safe care. Involvement of anesthesiologists in organizing services, training other practitioners, overseeing safety, systems, and quality, and remaining involved in the delivery of such care is sound practice. The elements of a safe system to provide procedural sedation for children are as follows:

- Defining the required knowledge set
- Defining the required skill set
- Determining the appropriate requisite training
- Ensuring adequate understanding of the drugs and their effects (desired and undesired) and interactions
- Credentialing providers
- Ensuring ongoing maintenance of skills
- Reviewing the practice
- Ensuring that the sites where anesthesia care is provided meet recognized standards
- Last but not least, overseeing a process of continuous quality improvement

Sedation with chloral hydrate (not approved by the FDA in the United States or the European Medicines Agency in the European Union), pentobarbital, or benzodiazepines is often adequate for nonpainful procedures. Nevertheless, there can be a high failure rate as well as complications by using this method, such as prolonged sedation (hours to overnight), ataxia, nausea and vomiting, desaturation, and the occasional need for rapid intervention. The temptation to add opioids and deepen sedation increases the risk of complications. The use of dexmedetomidine for procedural sedation is safe; recovery time can be prolonged, and success can be variable. The quickest way to ensure safely reversible sedation is with potent anesthetic agents.

Bibliography
The ultra–short-acting anesthetics (propofol, methohexital, remifentanil) provide effective procedural sedation, but their use carries a higher likelihood of inadvertent oversedation and induction of general anesthesia. These anesthetics offer efficient and rapidly reversible procedural sedation. However, their use requires the presence of an anesthesiologist and/or specially trained, experienced, and qualified physicians.

Bibliography is available at Expert Consult.

61.2 Anesthetic Neurotoxicity

Randall C. Wetzel

There is compelling experimental evidence that anesthesia-induced neurodegeneration with developmental impairment occurs in neonatal animals. Pediatric anesthesiologists have become deeply concerned by the demonstration of anesthetic-induced apoptotic neuronal cell death, central nervous system neurodegenerative changes, and their effects on the developing brain. These studies demonstrate both histopathologic changes and developmental defects from both inhalational and IV anesthetics, including isoflurane, ketamine, benzodiazepines, and propofol given to newborn animals. Combinations of drugs may cause more injury. Existing nonclinical data implicate both N-methyl-D-aspartate and γ-aminobutyric acid pathways in apoptosis and cell death in neonates.

The studies reporting these results were performed in animals (largely rodents), and great controversy exists concerning dose, duration of treatment, species differences, and experimental design. Although there is cause for concern and further study, alternatives to general anesthesia for many procedures in infants do not exist. Perhaps regional anesthetic techniques and narcotic-based anesthetics will be increasingly used. Interestingly, dexmedetomidine appears to block the neurotoxic effects of other anesthetics. There is insufficient current data for suggesting the safety of one anesthetic approach over another. The potential for this neurotoxicity must be balanced against the necessity of providing adequate anesthesia for neonates.

Bibliography is available at Expert Consult.
Bibliography

Pain is both a sensory and an emotional experience that, when unrecognized and undertreated, extracts a significant physiologic, biochemical, and psychologic toll. Many disease processes and most interventional procedures in pediatrics are associated with pain.

DEFINITION AND CATEGORIES OF PAIN

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." The important elements of this definition to be emphasized are (1) pain encompasses both peripheral physiologic and central cognitive/emotional components and (2) pain may or may not be associated with ongoing tissue damage—pain may exist in the absence of demonstrable somatic pathology, and may rather be the acquired or genetic consequence of abnormalities of peripheral neural signaling, central modulation, or brain processing of peripheral sensations or nociception.

Table 62-1 specifies important pain categories commonly treated (somatic, visceral, and neuropathic) and defines the elements and characteristics of nociception, the peripheral physiologic aspect of pain perception (Fig. 62-1). Nociception refers to how specialized fibers (largely, but not exclusively, the small unmyelinated A-delta and C fibers) in the peripheral nervous system transmit nerve impulses (usually transmitting signals originating from peripheral mechanoreceptors and chemoreceptors) through synapses in the spinal cord's dorsal horn through (but not exclusively through) the spinothalamic tracts to the brain's higher centers, where nociception is converted to pain, with all of its cognitive and emotional ramifications.

THE ASSESSMENT AND MEASUREMENT OF PAIN IN CHILDREN

Whenever feasible, the physician should ask the patient about the character, location, quality, duration, frequency, and intensity of the pain. Some children may not report pain because of fears (often well-founded) of talking to strangers, disappointing or bothering others, receiving an injection if they report pain, returning to the hospital if they admit to pain, and other negative possible reactions. For infants and nonverbal children, their parents, pediatricians, nurses, and other caregivers are constantly challenged to interpret whether the child's distressed behaviors represent pain, fear, hunger, or a range of other perceptions or emotions. Therapeutic trials of comfort measures (cuddling, feeding) and analgesic medications may be helpful in clarifying the triggers of the behaviors.

Behavior and physiologic signs are useful, but they can be misleading. A toddler may scream and grimace during an ear examination because of fear rather than pain. Conversely, children with inadequately relieved persistent pain from cancer, sickle cell disease, trauma, or surgery may withdraw from their surroundings and appear very quiet, leading observers to conclude falsely that they are comfortable or sedated. In these situations, increased dosing of analgesics may make the child become more, not less, interactive and alert. Similarly, neonates and young infants may close their eyes, furrow their brows, and clench their fists in response to pain. Adequate analgesia is often associated with eye opening and increased involvement in the surroundings. A child who is experiencing significant chronic pain may play normally as a way to distract attention away from pain. This coping behavior is sometimes misinterpreted as evidence of the child's "faking" or exaggerating pain at other times.

Age-Specific and Developmentally Specific Measures

Because infants, young children, and nonverbal children cannot express the quantity of pain they experience, several pain scales have been devised in an attempt to quantify pain in these populations (Fig. 62-2; Table 62-2).

The Newborn and Infant

There are several behavioral distress scales for the infant and young child, mostly emphasizing the patient's facial expressions, crying, and body movement. Facial expression measures appear most useful and specific in neonates. Autonomic and vital signs can indicate pain, but because they are nonspecific, they may reflect other processes, including fever, hypoxemia, and cardiac or renal dysfunction.

The Older Child

Children ages 3-7 yr become increasingly articulate in describing the intensity, location, and quality of pain. Pain is occasionally referred to adjacent areas; referral of hip pain to the leg or knee is common in this age range. Self-report measures for children this age include using drawings, pictures of faces, or graded color intensities. Children age 8 yr and older can usually use verbal numerical rating scales or visual analog pain scales accurately (see Fig. 62-2). Verbal numerical ratings are preferred and considered the gold standard; valid and reliable ratings can be obtained from children 8 yr and older. The Numerical
Rating Scale consists of numbers from 0-10, in which 0 represents no pain and 10 represents very severe pain. There is debate about the label for the highest pain rating, but the current agreement is not to use the term “worst pain possible,” because children can always imagine a greater pain. In the United States, regularly documented pain assessments are required for hospitalized children and children attending outpatient hospital clinics and emergency departments. Pain scores do not always correlate with changes in heart rate or blood pressure.

The Cognitively Impaired Child
Measuring pain in cognitively impaired children remains a challenge. Understanding pain expression and experience in this population is important, because behaviors may be misinterpreted as indicating that cognitively impaired children are more insensitive to pain than cognitively competent children. Children with trisomy 21 may express pain less precisely and more slowly than the general population. Pain in children with autism spectrum disorders may be difficult to assess because these children may be both hyposensitive and hypersensitive to many different types of sensory stimuli, and they may have limited communication abilities. Although self-reports of pain can be elicited from some children who are cognitively impaired, observational measures have better validation among these children. The Noncommunicating Child's Pain Checklist—Postoperative Version is recommended for children up to 18 yr. Maladaptive behaviors and reduction in functions may also indicate pain. Children with severe cognitive impairments frequently experience pain.

A CONCEPTUAL FRAMEWORK FOR THE TREATMENT OF PEDIATRIC PAIN
A number of models have been developed to understand the various factors that influence children's pain. Many of these theories focus on factors that explain the interindividual variability in pain perception, and the chronicity and impairment experienced with pain. Central to these models are interrelationships among biologic, cognitive, affective, and social factors that influence children's pain and disability, commonly referred to as biopsychosocial models of pain. Biologic factors include the child’s physical health, central nervous system factors (pain processing), sex, pubertal status, and genetic factors.

Behavioral Indicators

Facial grimacing: The Neonatal Facial Coding System uses several facial actions that may be indicators of pain. Pain is characterized by a bulging brow with tight creases in between; tightly closed eyelids; a deeply furrowed nasolabial groove; a horizontal, wide opened mouth; and a taut tongue that may be quivering along with the chin.

Crying: May be an indicator of pain.

Activity: Withdrawal or immobilization of a limb may be an indicator of pain.

Response to comfort measures: Feeding, swaddling, holding, and ensuring that the infant is neither wet nor cold may help to discriminate between pain and other conditions.

Physiologic indicators: Alterations in heart rate, blood pressure, \( \text{SpO}_2 \), respiratory rate, or alterations in pattern of respiration may be nonspecific indicators of pain.

Multidimensional Instrument

**FLACC** Scoring System: May be used in preverbal, mechanically ventilated, or cognitively impaired patients; it is an acronym that includes five indicators, each scored as a 0, 1, or 2 that forms a ten-point composite scale with a range from "0" (no pain) to "10" (worst pain).

**FLACC**: Score each category between 0 and 2. The total score may be any number from 0 to 10.

Self-Report of Pain

Categorical description: Toddlers or young children are asked to say if they are having "a little bit," a "middle amount," or "a lot" of pain.

Faces Scales: Children who do not have an appreciation of ordinal numbering are asked to rate their pain based upon cartoons depicting facial indicators of distress.

NRS: Older children and teenagers are asked to rate their pain on a scale of "0" (no pain) to "10" (worst pain).

VAS: Children or teenagers are asked to move an indicator along a mechanical slide to depict the level of pain; the clinician reads a number along a 10-cm indicator on the back to determine the numeric score.

Individual child cognitive and affective factors related to perception of pain are anxiety, fear, negative affect, pain behaviors, and functional disability, whereas social factors include such areas as culture, socio-economic status, school environment, social and peer interactions, and parental and family factors.

A framework that considers the interplay of biologic, psychologic, and social factors is useful for understanding pediatric pain and to guide pain assessment and the delivery of both pharmacologic and nonpharmacologic interventions for pain management. Many simple interventions designed to promote relaxation and patient control can be expected to work synergistically with pain medications for optimal relief of pain and related distress. Moreover, psychologic interventions are often coupled with physical therapy interventions to assist in the management of disabling chronic pain.

Pharmacologic Treatment of Pain
Developmental Pharmacology

The pharmacokinetics and pharmacodynamics of analgesics vary with age; drug responses in infants and young children differ from those in older children and adults. The elimination half-life of most analgesics is prolonged in neonates and young infants because of their immature hepatic enzyme systems and glomerular filtration. Clearance of
analgesics may also be variable in young infants and children. Renal blood flow, glomerular filtration, and tubular secretion increase dramatically in the 1st few weeks, approaching adult values by 3-5 mo of age. Renal clearance of analgesics is often greater in toddlers and preschool-age children than in adults, whereas in premature infants clearance is reduced. Age-related differences in body composition and protein binding also exist. Total-body water as a fraction of body mass increases in neonates, particularly in the 1st few weeks, approaching adult values by 3-5 yr and older. In young children, body composition changes with advancing age; total body water decreases and percentage of body fat increases. Because of decreased serum concentrations of albumin and α1-acid glycoprotein, neonates have reduced protein binding of some drugs, resulting in higher amounts of free, unbound, pharmacologic or antiplatelet effects of aspirin and NSAIDs, making it a particularly useful drug in patients with cancer. Unlike aspirin and NSAIDs, acetaminophen has only mild antiinflammatory action.

Acetaminophen toxicity can result from either a large single dose or cumulative, excessive dosing over days or weeks (see Chapters 63 and 363). A single, massive overdose overwhelms the normal glucuronidation and sulfation metabolic pathways in the liver, whereas long-term overdosing exhausts supplies of the sulfhydryl donor glutathione, leading to alternative cytochrome P450–catalyzed oxidative metabolism and the production of the hepatotoxic metabolite N-acetyl-p-benzoquinone imine (NAPQI). Toxicity manifests as fulminant hepatic necrosis and failure in infants, children, and adults. Drug biotransformation processes are immature in neonates, very active in young children, and somewhat less active in adults. Young children are more resistant to acetaminophen-induced hepatotoxicity than are adults as a result of metabolism differences: Sulfation predominates over glucuronidation in young children, leading to a reduction in N-acetyl-p-benzoquinone imine production.

**Acetaminophen, Aspirin, Nonsteroidal Antiinflammatory, and Coxib Drugs**

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) have replaced aspirin as the most commonly used antipyretics and oral, nonopioid analgesics (Table 62-3).

**Acetaminophen**, a generally safe, nonopioid analgesic and antipyretic, has the advantage of intravenous, rectal, and oral routes of administration. Acetaminophen is not associated with the gastrointestinal or antiplatelet effects of aspirin and NSAIDs, making it a

<td>Allow 2 min before starting procedure; analgesia may last up to 8 min; the dose may be repeated once</td>
</tr>
</tbody>
</table>

FDA, U.S. Food and Drug Administration; IV, intravenously(ly); NSAIDs, nonsteroidal antiinflammatory drugs; PDD, pervasive developmental disorder; PDR, Physicians’ Desk Reference; PR, per rectum; QTc, corrected QT interval on an electrocardiogram; SSRI, selective serotonin reuptake inhibitor.

(found in gastric mucosa and platelets) and COX-2 (active in inflammatory pathways and cortical renal blood flow regulation) enzymes that synthesize prostaglandins. In children with juvenile idiopathic arthritis, ibuprofen and aspirin are equally effective, but ibuprofen is associated with fewer side effects and better drug adherence. NSAIDs and coxibs used adjunctively in surgical patients reduce opioid requirements (and, therefore, opioid side effects) by as much as 35-40%. Although NSAIDs can be useful postoperatively, they should be used as an adjunct to, not as a substitute for, opioids in patients with moderate to severe pain.

Ketorolac, an IV or intranasal NSAID, is useful in treating moderate to severe acute pain in patients who are unable or unwilling to swallow oral NSAIDs. Intravenous ibuprofen is approved in the United States for the management of pain and fever for 5 days or fewer, although there is no pediatric indication in the package labeling. In Europe, IV ibuprofen is used to treat pediatric pain.

Adverse effects of NSAIDs are uncommon, but they may be serious when they occur. They include loss of bone growth and healing; gastritis with pain and bleeding; decreased renal blood flow that may reduce glomerular filtration and enhance sodium reabsorption, in some cases leading to tubular necrosis; hepatic dysfunction and liver failure; inhibition of platelet function; and an increased incidence of cardiovascular events in patients predisposed to stroke and myocardial infarction. Although the overall incidence of bleeding is very low, gastric bleeding is the most common cause of mortality related to this class of analgesics.

NSAIDs should not be used in the child with a bleeding diathesis or at risk for bleeding or when surgical hemostasis is a concern, such as after tonsillectomy. The drug class is usually avoided in the setting of bone healing, except perhaps in the first few days following surgery.

Renal injury from short-term use of ibuprofen in euvolemic children is quite rare; the risk is increased by hypovolemia or cardiac...
dysfunction. The safety of both ibuprofen and acetaminophen for short-term use is well established (see Table 62-3).

Coxib drugs available in the United States are limited to oral celecoxib, whereas in Europe and elsewhere parenteral parecoxib and oral rofecoxib are available (parecoxib was not approved for use in the United States, while rofecoxib was approved and withdrawn from the market because of concern of enhancement of the risk of heart attacks and stroke, which was subsequently found to be associated with all the coxibs and NSAID drugs as well). The coxib drugs are selective COX-2 enzyme inhibitors; therefore they are effective antiinflammatory and analgesic molecules that generally do not result in platelet inhibition and bleeding or in gastric inflammation or ulceration, findings that may be seen with the nonselective COX inhibitors in the NSAID class. However, coxib drugs do inhibit regulation of cortical renal blood flow, and therefore carry the same risk of renal dysfunction and acute tubular necrosis. Celecoxib is therefore an appropriate primary or adjunctive analgesic to use in children following surgery, children with gastric mucosal pathology, or oncology patients in whom concern for hemostasis contraindicates conventional NSAIDs.

**Opioids**

Opioids are analgesic substances either derived from the opium poppy (opiates) or synthesized to have a similar chemical structure and mechanism of action (opioids). The older, pejorative term narcotics should not be used for these agents, because it connotes criminality and lacks pharmacologic descriptive specificity. Opioids are administered for moderate and severe pain, such as acute postoperative pain, sickle cell crisis pain, and cancer pain. Opioids can be administered by the oral, rectal, oral transmucosal, transdermal, intranasal, IV, epidural, intrathecal, subcutaneous, or intramuscular route. Historically, infants and young children have been underdosed with opioids for fear of significant respiratory side effects. In contrast, the use of opioids for moderate-to-severe noncancer pain does not have the evidence base that their use in cancer-associated pain does. There is concern for the potential for unwarranted use of opioids to increase the incidence of side effects. With proper understanding of the pharmacokinetic and pharmacodynamics of opioids, children can receive effective relief of pain and suffering with a good margin of safety (Tables 62-4 to 62-7).

Opioids act by mimicking the actions of endogenous opioid peptides, binding to receptors in the brain, brainstem, spinal cord, and peripheral nervous system, and thus leading to inhibition of nociception. Opioids have dose-dependent respiratory depressant effects, and they blunt ventilatory responses to hypoxia and hypercarbia. These respiratory depressant effects can be increased with coadministration of other sedating drugs, such as benzodiazepines or barbiturates. What was once thought to represent infants’ particular sensitivity to the opioids’ respiratory depressant effects we now understand to be a result of infants’ lower metabolic clearance of opioids and higher blood levels with frequent dosing.

Optimal use of opioids requires proactive and anticipatory management of side effects (see Table 62-6). Common side effects include constipation, nausea, vomiting, urinary retention, and pruritus. The most common, troubling, but treatable side effect is constipation. Stool softeners and stimulant laxatives should be administered to most patients receiving opioids for more than a few days. Constipation also remains a problem with long-term opioid administration. A peripherally acting opiate μ-receptor antagonist, methylnaltrexone, promptly and effectively reverses opioid-induced constipation in patients with chronic pain who are receiving opioids daily. In addition lubiprostone, an epithelial chloride channel agent, has been approved for the treatment of opioid-induced constipation in adults with chronic noncancer pain. The side effect of nausea typically subsides with long-term dosing, but it may require treatment with antiemetics, such as a phenothiazine, butyrophenones, antihistamines, or a serotonin receptor antagonist such as ondansetron or granisetron. Pruritus and other complications during patient-controlled analgesia (PCA) with opioids may be effectively managed by low-dose IV naloxone (see Table 62-6).

One of the potent barriers to effective management of pain with opioids is the unrealistic fear of addiction held by many prescribing pediatricians and parents. Pediatricians should understand the phenomena of tolerance, dependence, withdrawal, and addiction (see Table 62-5) and should know that the rational short- or long-term use of opioids in children does not lead to a predilection or risk of addiction in a child not otherwise at risk by virtue of genetic background and social milieu. It is important for pediatricians to realize that even patients with recognized substance-abuse diagnoses are entitled to effective analgesic management, which often includes the use of opioids. When there are legitimate concerns about addiction in a patient, then safe, effective opioid pain management is often best managed by specialists in pain management and/or addiction medicine.

There is no longer a reason to administer opioids by intramuscular injection. Continuous IV infusion of opioids is an effective option that permits more constant plasma concentrations and clinical effects than intermittent IV bolus dosing, without the pain associated with intramuscular injection. The most common approach in pediatric centers is to administer a low-dose basal opioid infusion, while permitting patients to use a patient-controlled analgesia (PCA) device to titrate the dosage above the infusion (see Chapter 61; Fig. 62-3). Compared with children given intermittent intramuscular morphine, children using PCA reported better pain scores. PCA has several other advantages: (1) dosing can be adjusted to account for individual pharmacokinetic and pharmacodynamic variation and for changing pain intensity during the day; (2) psychologically, the patient is more in control, actively coping with the pain; (3) overall opioid consumption is lower; (4) fewer side effects occur; and (5) patient satisfaction is generally much higher. Children as young as 5-6 yr can effectively use PCA. The device can be activated by parents or nurses—the latter practice known as PCA-by-proxy; PCA-by-proxy produces analgesia in a safe, effective manner for children who cannot activate the PCA demand button themselves because they are too young or intellectually or physically impaired. PCA overdoses occur when well-meaning, inadequately instructed parents pushed the PCA button in medically complicated situations with or without the use of PCA-by-proxy, highlighting the need for patient and family education, the use of protocols, and adequate nursing supervision.

**Local Anesthetics**

Local anesthetics are widely used in children for topical application, cutaneous infiltration, peripheral nerve block, epidural neuroaxial blocks, intrathecal infusions, and IV infusions (see Chapter 61; Table 62-8). Local anesthetics can be used with excellent safety and effectiveness. Local anesthetics interfere with neural transmission by blocking sodium channels. Excessive systemic dosing can cause seizures, central nervous system (CNS) depression, and by cardiac and arteriolar sodium channel blockade hypotension, arrhythmias, cardiac...

Management of Opioid-Induced Adverse Effects

<table>
<thead>
<tr>
<th>Table 62-6</th>
<th>Management of Opioid-Induced Adverse Effects</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Respiratory depression</strong></td>
<td>Naloxone: 0.01-0.02 mg/kg up to a full reversal dose of 0.1 mg/kg. May be given IV, IM, subcutaneously (SC), or via endotracheal tube (ET). The full reversal dose should initially be used for apnea in opioid-naïve patients. In opioid-tolerant patients, a reduced dose should be given and titrated up slowly to treat symptoms but prevent acute withdrawal. Ventilation may need to be supported during this process. Dose may be repeated every 2 min to a total of 10 mg. Adult maximum dose is 2 mg/dose. Give with caution to patients who are receiving long-term opioid therapy, as it may precipitate acute withdrawal. Duration of effect is 1-4 hr; therefore, close observation for renarcotization is essential.</td>
</tr>
<tr>
<td><strong>Excessive sedation without evidence of respiratory depression</strong></td>
<td>Methylphenidate(^*): 0.3 mg/kg per dose PO (typically 10-20 mg/dose to a teenager) before breakfast and lunch. Do not administer to patients receiving clonidine, because dysrhythmias may develop. Dextroamphetamine: 2.5-10 mg on awakening and at noon. Not for use in young children or in patients with cardiovascular disease or hypertension. Modafinil: Pediatric dose not established. May be useful in selected patients. Typical adult dose: 50-200 mg/day. Change opioid or decrease dose.</td>
</tr>
<tr>
<td><strong>Nausea and vomiting</strong></td>
<td>Metoclopramide(^1): 0.15 mg/kg IV up to 10 mg/dose q6-12h for 24 hr. Trimethobenzamide: PO or rectally (PR) if weight &lt;15 kg, 100 mg q6h; if &gt;15 kg, 200 mg q6h. (Note: Suppository contains benzoic acid.) Not for use in newborn infants or premature infants. 5-HT(_3) blockers: Ondansetron: 0.15 mg/kg up to 8 mg IV q6-8h not to exceed 32 mg/day (also available as a sublingual tablet). Granisetron: 10-20 µg/kg IV q12-24h. Prochlorperazine(^\ast): (Compazine): &gt;2 yr or &gt;20 kg, 0.1 mg/kg per dose q6h IM or PO up to 10 mg/dose. Change opioid.</td>
</tr>
<tr>
<td><strong>Pruritus</strong></td>
<td>Hydroxyzine: 0.5 mg/kg PO q6h. Nalbuphine: 0.1 mg/kg IV q6h for pruritus caused by intraaxial opioids, especially fentanyl. Administer slowly over 15-20 min. May cause acute reversal of systemic (\mu)-receptor effects and leave (\kappa)-agonism intact. Naloxone: 0.003-0.1 mg/kg/hr IV infusion (titrate up to decrease pruritus and reduce infusion if pain increases). Ondansetron: 0.05-0.1 mg/kg IV or PO q8h. Cyproheptadine(^1): 0.1-0.2 mg/kg PO q8-12h. Maximum dose 12 mg. Change opioid.</td>
</tr>
<tr>
<td><strong>Constipation</strong></td>
<td>Encourage water consumption, high-fiber diet, and vegetable roughage. Bulk laxatives: Metamucil, Maltasupex. Lubricants: Mineral oil 15-30 mL PO qd as needed (not for use in infants because of aspiration risk). Surfactants: Sodium docusate (Colace): &lt;3 yr: 10 mg PO q8h 3-6 yr: 15 mg PO q8h 6-12 yr: 50 mg PO q8h &gt;12 yr: 100 mg PO q8h Stimulants: Bisacodyl suppository (Dulcolax): &lt;2 yr: 5 mg PR qhs &gt;2 yr: 10 mg PR qhs Senna syrup (218 mg/5 mL): &gt;3 yr, 5 mL qhs. Enema: Fleet’s hypertonic phosphate enema (older children; risk of hyperphosphatemia). Electrolytic/osmotic: Milk of magnesia; for severe impaction: polyethylene glycol (GoLYTELY, MiraLAX).</td>
</tr>
</tbody>
</table>

*Avoid in patients taking monoamine oxidase inhibitors.

1 May be associated with extrapyramidal side effects, which may be more commonly seen in children than in adults.

**PERIPHERAL NERVOUS SYSTEM FOCAL AND MULTIFOCAL LESIONS**
- Postherpetic neuralgia
- Cranial neuralgias (such as trigeminal neuralgia, glossopharyngeal neuralgia)
- Diabetic mononeuropathy
- Nerve entrapment syndromes
- Plexopathy from malignancy or irradiation
- Phantom limb pain
- Posttraumatic neuralgia (such as nerve root compression after thoracotomy)
- Ischemic neuropathy

**PERIPHERAL NERVOUS SYSTEM GENERALIZED POLYNEUROPATHIES**
- Metabolic/nutritional: Diabetes mellitus, pellagra, beriberi, multiple nutritional deficiency, hypothyroidism
- Toxic: Alcohol-, platinum-, or taxane-based chemotherapy, isoniazid, antiretroviral drugs
- Infective/autoimmune: HIV, acute inflammatory polyneuropathy (Guillain-Barré syndrome), neuroborreliosis (Bannwarth syndrome)
- Hereditary: Fabry disease
- Malignancy: Carcinomatosis
- Others: Idiopathic small fiber neuropathy

**CENTRAL NERVOUS SYSTEM LESIONS**
- Spinal cord injury
- Pseudosepse disc
- Stroke (brain infarction, spinal infarction)
- Multiple sclerosis
- Surgical lesions (such as rhizotomy, cordotomy)
- Complex neuropathic disorders
- Complex regional pain syndrome types I and II

**Notes:**
- Published reports vary in the suggested doses considered to be equianalgesic to morphine. Therefore, titration to clinical response in each patient is necessary.
- Suggested doses are the results of single-dose studies only. Therefore, use of the data to calculate total daily dose requirements and repeated or continuous doses may not be appropriate.
- There may be incomplete cross-tolerance between these drugs. In patients who have been receiving 1 opioid for a prolonged period, it is usually necessary to use a dose lower than the expected equianalgesic dose when changing to another opioid, and to titrate to effect.
- Rapidly hydrolyzed to morphine.
- Only part of its analgesic action results from action on β opioid receptors.

- depression, and cardiovascular collapse. Unlike opioids, local anesthetics therefore require a strict maximum dosing schedule. Pediatricians should be aware of the need to calculate these doses and adhere to guidelines.

- Topical local anesthetic preparations do not generally result in measurable systemic blood levels, and can reduce pain in diverse circumstances: suturing of lacerations, placement of peripheral IV catheters, lumbar punctures, and accessing of indwelling central venous ports. The application of tetracaine, epinephrine, and cocaine (TAC) results in good anesthesia for suturing wounds, but TAC should not be used on mucous membranes. Combinations of tetracaine with phenyleph-

*MISCELLANEOUS* includes antiepileptic drugs (AEDs), and neurotropic drugs.

**UNCONVENTIONAL MEDICATIONS IN PEDIATRIC PAIN**

Unconventional analgesic medication refers to a wide number of drugs that were developed for other indications but that have been found to have analgesic properties. These drugs include some antidepressants, antiepileptic drugs (AEDs), and neurotropic drugs.

The unconventional analgesics are generally used to manage neuropathic pain conditions, migraine disorders, fibromyalgia syndrome, and some forms of functional chronic abdominal pain syndromes, but they are generally not used to manage surgical, somatic, or musculoskeletal pain. Figure 62-4 presents a decision-making tree that will help the physician select the appropriate analgesic category for various types of pain. The AED gabapentin confers analgesia as well as opioid-sparing benefits following major surgery in adults and in one well-conducted clinical trial in adolescents following spine surgery.

Although several unconventional analgesics have been approved by the FDA for analgesic uses, none has been specifically approved for use in youth with chronic pain. Thus, these drugs should be used with caution, with a focus on mitigating pain to allow a child to participate effectively in therapies and return to normal activity as soon as possible. The use of psychotropic medications should be guided by the principles applied to pharmacologic treatment of any symptom or disease. Target symptoms should be identified, and medication side effects monitored. To determine dosing regimens, the physician should consider the child’s weight and the effects that medical condition and other medications, such as psychotropic drugs, may have on the child’s metabolism. When available, therapeutic blood-level monitoring should be performed. Side effects should be addressed in detail with both parent and child, and specific instructions given for responding to possible adverse events. It may be necessary to directly address concerns about addiction, dependence, and tolerance in order to decrease treatment-related anxiety and improve medication adherence.

**Antidepressant Medications**

Antidepressant medications are useful in adults with chronic pain, including neuropathic pain, headaches, and rheumatoid arthritis, independent of their effects on depressive disorders. Antidepressants’ analgesic properties inhibit norepinephrine reuptake in the CNS. In children, because clinical trials have been limited, the practitioner should use antidepressants cautiously to treat chronic pain or associated depressive or anxiety symptoms. The FDA issued a “black box warning,” its strongest warning, to inform the public of a small but significant increase in suicidal thoughts and attempts in children and adolescents receiving antidepressants. A meta-analysis of studies involving children and adolescents receiving antidepressants indicated that no suicides had been completed. The pediatrician should address this issue with parents of patients being treated with antidepressants and should develop monitoring plans consistent with current FDA recommendations.

**Tricyclic Antidepressants**

Tricyclic antidepressants (TCAs), which have been studied most in children with chronic pain, are effective in pain relief for symptoms including neuropathic pain, functional abdominal pain, and migraine. The efficacy of TCAs may be based on inhibition of the neurochemical pathways involved in norepinephrine and serotonin reuptake and their interference with other neurochemicals involved in the perception or neural conduction of pain. Because sedation is the most common side effect of TCAs, these medications are also effective in treating the sleep disorders that frequently accompany pediatric pain. Biotransformation of TCAs is extensive in healthy children, so the child should be started on a bedtime dose, which may be able to then be titrated to a daily divided dose, with the larger dose given at bedtime. However, TCAs typically are administered only at bedtime. Pain symptoms usually remit at lower doses than those recommended or required for the treatment of mood disorders. Most children and adolescents do not require more than 0.25-0.5 mg/kg of amitriptyline or nortriptyline once a day at bedtime.

Attention should also be paid to hepatic microsomal enzyme metabolism, because CYP2D6 inhibitors, such as cimetidine and quinidine, can increase levels of TCAs. Anticholinergic side effects, which are remarkably uncommon in children in comparison with adults, often remit over time. Constipation, orthostatic hypotension, and...
Serotonin and Serotonin-Norepinephrine Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) have minimal efficacy in the treatment of a variety of pain syndromes in adults. SSRIs are very useful when symptoms of depression or anxiety disorders are present and cannot be addressed adequately by nonpharmacologic means. Although many SSRIs are used in practice with children, only fluoxetine has been approved by the FDA for use in children and adolescents. SSRIs have a significantly milder side-effect profile than do TCAs (most side effects of both are transient), and they have no anticholinergic side effects. Chief side effects include gastrointestinal symptoms, headaches, agitation, insomnia, sexual dysfunction, and anxiety. Rarely, hypotension, or the syndrome of inappropriate antidiuretic hormone secretion, may occur. Interactions with other medications that have serotonergic effects (trazodone, trazodone, tryptophan, and triptan migraine medication) may also occur. When these medications are used in combination, there is increased likelihood that a life-threatening serotoninergic syndrome may occur, with associated symptoms of myoclonus, hyperreflexia, autonomic instability, muscle rigidity, and delirium. There is also a discontinuation syndrome associated with shorter-acting SSRIs (paroxetine), which includes dizziness, lethargy, paresthesias, irritability, and vivid dreams. Dosages of medications should be tapered slowly over several weeks.

The selective serotonin-norepinephrine reuptake inhibitors duloxetine and venlafaxine demonstrate significant efficacy with chronic neuropathic and other pain syndromes because they inhibit both serotonin and norepinephrine reuptake, and they may directly block associated pain receptors as well. Venlafaxine has no pain indication labeling, but duloxetine is FDA approved for managing neuropathic pain (diabetic neuropathy) and fibromyalgia syndrome.

Because both SSRIs and selective serotonin-norepinephrine reuptake inhibitors have fewer anticholinergic side effects than TCAs, adherence to them is better than in psychiatric populations taking TCAs. Side effects of both types of drugs include gastrointestinal symptoms, hyperhidrosis, dizziness, and agitation, but these effects generally wane over time. Hypertension and orthostatic hypotension may occur; in addition, the patient’s blood pressure should be closely followed, and appropriate hydration should be stressed. Note that whereas appetite stimulation and weight gain are associated with all TCAs, duloxetine is often associated with weight loss, frequently a desirable side effect, especially in weight-conscious adolescent females.

Antiepileptic Drugs

Traditional anticonvulsants, such as carbamazepine and valproic acid, are believed to relieve chronic pain by blocking sodium (valproate and the gabapentinoids) or calcium channels (carbamazepine and oxcarbazepine) at the cellular neuronal level, thereby suppressing spontaneous electrical activity and restoring the normal threshold to depolarization of hypersensitive nociceptive neurons, without affecting normal nerve conduction. These medications are particularly useful in patients with mood disorders and neuropathic pain. In adults, the FDA has approved carbamazepine for trigeminal neuralgia and valproate for migraine prophylaxis, and pregabalin is approved in adults for neuropathic pain complicating diabetes, zoster, and for management of fibromyalgia. Anticonvulsant medications generally have gastrointestinal side effects in addition to sedation, anemia, ataxia, rash, and hepatitis toxicity. Carbamazepine and oxcarbazepine are associated with an increased incidence of Stevens-Johnson syndrome. Liver function values and a complete blood count should be obtained at start of therapy (baseline) and monitored with use of both these agents. These medications have narrow therapeutic windows and may have extreme variability in therapeutic blood medication levels, as well as multiple drug–drug interactions; also, they may produce liver disease and renal impairment. Drug levels should be measured with each dose increase and periodically thereafter. Carbamazepine, in particular, causes autoinduction of hepatic microsomal enzymes, which can further complicate obtaining a therapeutic medication level. Frequent pregnancy tests are useful in menstruating female adolescents taking valproate, because severe neural tube defects are associated with this medication.

Less-toxic AEDs have supplanted the use of valproate and carbamazepine in patients with pain. These agents have their own, sometimes troubling side effect profiles, but they are far less toxic than their predecessors and they do not require monitoring of liver function, bone marrow function, or therapeutic blood levels. They are also far less lethal in accidental or deliberate overdose.

Gabapentin, the most widely prescribed AED for the management of pain disorders, demonstrates efficacy in treating children with chronic pain, particularly neuropathic pain, and is playing an increasing role in the management of routine surgical pain. Gabapentin has proven effective in treating chronic headache disorders, and many neuropathic pain syndromes including complex regional pain syndromes, chemotherapy induced neuropathy, postherpetic neuralgia, and diabetic neuropathy in both children and adults. This agent has a relatively benign side-effect profile and few drug interactions. Side effects include somnolence, dizziness, and ataxia. Children occasionally demonstrate side effects not reported in adults—severe impulsive or oppositional behavior, agitation, and, occasionally, depression. These side effects do not seem to be dose related.

A molecularly similar AED, pregabalin, works by mechanisms similar to those of gabapentin but appears to have a better side-effect profile. Because it undergoes virtually no hepatic metabolism, pregabalin has no significant drug–drug interactions, a concern in patients with chronic pain, who frequently take multiple medications—for both the pain and the underlying medical condition associated with the pain.

Topiramate also demonstrates greater success than traditional anticonvulsants in treating trigeminal neuralgia in adults and in migraine prophylaxis. Topiramate therapy results more frequently in cognitive dysfunction and short-term memory loss compared with gabapentin or pregabalin, and these neurocognitive effects are particularly problematic for school-age children. The pediatrician should also be aware that in female adolescents, topiramate is associated with weight loss, whereas other anticonvulsants are typically associated with significant weight gain.

Benzodiazepines

Children and adolescents with chronic pain may have comorbid psychiatric conditions such as depressed mood, sleep disturbances, or anxiety disorders, including generalized anxiety disorder, separation anxiety, posttraumatic stress disorder, and panic attacks. Pervasive developmental disorders are also common in this population.
Psychologic factors can affect a youth's ability to cope with a pain disorder; a conditioned response to pain may be to feel out of control and to lead to increases in anxiety and pain. Conversely, the feeling of helplessness can sensitize the child to increasing amounts of pain, leading the child to perseverate on the pain, think catastrophically, and feel hopeless. Changes in children's normal routines, with a negative impact on participation in valued activities, may further promote hopelessness, resulting in increased pain experiences and development of a depressive disorder.

Benzodiazepines are anxiolytic medications that also have muscle relaxant effects. They are particularly appropriate in acute situations as valuable adjuncts to the management of pain in the hospital setting, because they inhibit painful muscle spasms in surgical patients, but more importantly because they suppress the anxiety that virtually every hospitalized child experiences, anxiety that interferes with restorative sleep and amplifies the child's perception of pain. Benzodiazepines are useful to calm children with anxiety and anticipatory anxiety about planned, painful procedures.

Because dependence, tolerance, and withdrawal may occur with prolonged use, benzodiazepines are generally not recommended for the routine management of chronic pain. In concert with psychotherapy, they help control anxiety symptoms that amplify the perception of pain. Infrequently, benzodiazepines may cause behavioral disinhibition, psychosis-like behaviors, or, in large doses, respiratory depression. When dosing these medications, the pediatrician should consider that many benzodiazepines are metabolized by the cytochrome P450 microsomal enzyme system. This issue may be less significant with lorazepam and oxazepam, which undergo 1st-pass hepatic conjugation. Side effects common to benzodiazepines include sedation, ataxia, anemia, increased bronchial secretions, and depressed mood. If a benzodiazepine is administered for more than several consecutive days, the dosage should be slowly tapered over 2 or more weeks; if therapy is abruptly discontinued, autonomic instability, delirium, seizures, and profound insomnia may occur. There are data that suggest that the use of benzodiazepines during hospitalization for serious disease, such as organ transplantation, might increase the risk of development of post-traumatic stress disorder.

**Antipsychotics and Major Sedatives**

Low doses of antipsychotic medications are often used to address more-severe anxiety and agitation sometimes associated with chronic pain. The use of these medications is controversial because the associated adverse events may be severe. Typical antipsychotics, including thioridazine (Mellaril), haloperidol (Haldol), and chlorpromazine (Thorazine), are associated with a decrease in seizure threshold, agranulocytosis, weight gain, cardiac conduction disturbances, tardive dyskinesia, orthostatic hypotension, hepatic dysfunction, and life-threatening laryngeal dystonia. These side effects are generally less severe with atypical antipsychotics. Because they may still occur, the pediatrician should obtain a baseline electrocardiogram, liver function tests, and complete blood count. If the pediatrician is using typical antipsychotics, an inventory of movement disturbances, such as the Abnormal Involuntary Movement Scale test, should be performed at baseline and at every follow-up visit, because movement disorders can worsen with abrupt withdrawal of medications or can become irreversible.

Atypical antipsychotics are generally associated with less-severe side-effect profiles, particularly with regard to side effects such as dyskinesias and dystonias. Use of olanzapine (Zyprexa), which is particularly helpful with insomnia and severe anxiety, requires assessing dyskinesias, orthostatic hypotension, hepatic dysfunction, and life-threatening agranulocytosis, which should generally be avoided as a treatment for children and adolescents with chronic pain. Aripiprazole (Abilify) has been used for severe anxiety and/or for treatment-resistant depression. All antipsychotics are associated with the rare, but potentially lethal neuroleptic malignant syndrome, which includes severe autonomic instability, muscular rigidity, hyperthermia, catatonia, and altered mental status.

**Nonpharmacologic Treatment of Pain**

Numerous psychologic and physical treatments for relieving pain, fear, and anxiety as well as enhancing functioning have been a mainstay of pediatric pain treatment and have excellent safety profiles and proven effectiveness. In the area of acute and procedural pain, nonpharmacologic strategies have long been used to help reduce distress in children undergoing medical procedures and surgery. Many of the behavioral methods aim to help children shift attention from pain and alter pain perception (e.g., distraction, hypnosis, imagery). In the treatment of chronic pain, cognitive-behavioral therapies (CBTs) are the most implemented nonpharmacologic treatment. CBT was developed with the goal of modifying social/environmental and behavioral factors that may exacerbate the child's experience of pain and pain-related disability. There are now several decades of research available on CBTs for pediatric chronic pain. Meta-analyses of randomized controlled trials of CBT interventions have found large positive effects of psychologic intervention on pain reduction in children with headache, abdominal pain, and fibromyalgia. Effective strategies include cognitive-behavioral skills training, parent training, relaxation therapy, and biofeedback. The relative or comparative effectiveness of different interventions has been examined in studies of headache and abdominal pain in children. Biofeedback and relaxation therapies have been found to have superior effects to pharmacologic treatments in reducing headache pain in children and adolescents. Similarly, for recurrent abdominal pain, positive effects for CBT were found relative to pharmaceutical, botanical, and dietary interventions (which had very weak evidence).

Nonpharmacologic treatments of pain may be generalized to other treatment needs. A child with cancer who learns self-hypnosis to reduce distress from lumbar punctures may successfully apply this skill to other stressful medical and nonmedical situations. When deciding how to incorporate nonpharmacologic techniques to treat pain, the practitioner should: (1) pay attention to the patient's environment, optimal positioning, and physical comfort; (2) seek to integrate nonpharmacologic techniques with appropriate analgesics; (3) give children (and family members) developmentally and situationally appropriate information as to what to expect, given the child's medical condition, procedures, and treatments; (4) include patients and their families in decision making to ensure an appropriate treatment choice and to optimize adherence to treatment protocols; and (5) above all, develop a communication plan among the different therapists, typically with the pediatrician as the case manager, so that the messages to the child and parent are consistent and the modes of therapy are organized into an integrative team approach.

**Cognitive-behavioral strategies** refer to techniques that teach children how to manage pain by learning new ways to think about the pain and to change behaviors associated with the pain. This includes strategies aimed at enhancing children's confidence and self-efficacy, decreasing fear of pain, and promoting exposure to previously avoided activities. In addition, pain coping skills may shift the child's attentional focus away from pain and painful stimuli. Behavioral strategies focused on modifying contingencies in the child's environment (such as parental responses to pain behaviors) may influence pain expression, leading to changes in how children behave or respond to pain. Strategies may also be aimed specifically at modifying individual and family coping (e.g., difficulties in social relationships, psychosocial distress).

**Parent and family education and/or psychotherapy**, particularly cognitive-behavioral family approaches, have been shown to be effective for treating chronic pain. Parents can learn to cope with their own distress and to understand pain mechanisms and appropriate treatment of pain. Key strategies include teaching parents to alter family patterns that may inadvertently exacerbate pain through developing behavior plans. Parents are taught to create plans for the child to manage the child's own symptoms and increase independent functioning. Often, all adult caregivers (e.g., parents and teachers) need
guidance on developing a behavioral incentive plan to help the child return to school, gradually increase attendance, and receive tutoring, after a prolonged, pain-related absence.

Other Psychologic or Psychiatric Treatment
In addition to pain, there may be other psychologic disorders (e.g., anxiety disorders, major depression) that should be identified and addressed either as part of or separate from the pain management plan. Individual psychotherapy or psychiatric intervention may be warranted to adequately treat a comorbid disorder. Relaxation techniques promote muscle relaxation and reduction of anxiety, which often accompanies and increases pain. Controlled breathing and progressive muscle relaxation are commonly used relaxation techniques for preschool-age and older children. Asking the child to focus on the breath and pretend to be blowing up a big balloon, while pursing the lips and exhaling slowly may help induce controlled breathing. Distraction helps a child of any age shift attention away from pain and onto other activities. Common attention sustainers in the environment include bubbles, music, video games, television, the telephone, conversation, school, and play. Asking children to tell stories, or asking parents to read to the child, and even mutual story-telling can be helpful distracters. Being involved with social, school, physical, or other activities helps the child in chronic pain to regain function. Hypnotherapy helps a child focus on an imaginative experience that is comforting, safe, fun, or intriguing. Hypnotherapy captures the child’s attention, alters his sensory experiences, reduces distress, reframes pain experiences, creates time distortions, helps the child dissociate from the pain, and enhances feelings of mastery and self-control. Children with chronic pain can use metaphor, for example, imagining they have overcome something feared because of pain in real life. As the child increases mastery of imagined experiences, the enhanced sense of control can be used during actual pain rehabilitation. Hypnotherapy is best for children of school age or older. Biofeedback involves controlled breathing, relaxation, or hypnotic techniques with a mechanical device that provides visual or auditory feedback to the child when the desired action is approximated. Common targets of actions include muscle tension, peripheral skin temperature through peripheral vasodilation, and anal control through rectal muscle contraction and relaxation. Biofeedback also enhances the child’s sense of mastery and control, especially for the child who needs more “proof” of change than that generated through hypnotherapy alone. Iyengar yoga was developed to achieve balance in mind, body, and spirit. This form of therapeutic yoga is especially effective for treating chronic pain; improving mood, energy, and sleep; and reducing anxiety. Iyengar yoga involves a series of asanas (body poses) oriented to the specific medical condition or symptoms. It uses props, such as blankets, bolsters, blocks, and belts, to support the body while the patient assumes more healing poses. Yoga promotes a sense of energy, relaxation, strength, balance, and flexibility and, over time, enhances a sense of mastery and control. In more advanced yoga, the child may learn certain types of breathing (pranayama) for added benefit. Mostly, through this form of yoga, the child learns mindfulness or being present and in the moment. By focusing on body and breath, the child can develop strategies to avoid ruminating about the past or worrying about the future.

Massage therapy involves the therapist’s touching and applying varied degrees of pressure on the child’s muscles. This massage is very useful for children with chronic pain and especially helpful for those with myofascial pain. There are several types of massage, including craniosacral therapy. For young children, it can be helpful to have parents learn and perform brief massage on their children before bedtime. Physical therapy can be especially useful for children with chronic, musculoskeletal pain, and for those deconditioned from inactivity. Exercise appears to specifically benefit muscle functioning, circulation, and posture, also improving body image, body mechanics, sleep, and mood. The physical therapist and the child can develop a graded exercise plan for enhancing the child’s overall function.

Acupuncture involves the placement of needles at specific acupuncture points along a meridian, or energy field, after a diagnosis of excess or deficient energy in that meridian as the primary cause of the pain is made by the acupuncturist. Acupuncture is a feasible, popular part of a pain management plan for children with chronic pain. Acupuncture alleviates chronic nausea, fatigue, and several chronic pain states, including migraine and chronic daily headaches, abdominal pain, and myofascial pain. Acupuncture also has efficacy in adults with myofascial pain, primary dysmenorrhea, sickle cell crisis pain, and sore throat pain. The acupuncturist must relate well to children so that the experience is not traumatic, because added stress would undo the benefits gained. Transcutaneous electrical nerve stimulation (TENS) is the use of a battery-operated tool worn on the body to send electrical impulses into the body at certain frequencies set by the machine. TENS is believed to be quite safe and can be tried for many forms of localized pain. Children often find TENS helpful and effective. Music and art therapy can be especially helpful for young and nonverbal children who would otherwise have trouble with traditional talk psychotherapies. Also, many creative children can more easily express fears and negative emotions through creative expression and, with the therapist’s help, learn about themselves in the process. Dance, movement, pet therapies, and aromatherapy have also been used and may be very helpful but have not been well studied in children for pain control.

Invasive Interventions in Treating Pain
Interventional neuraxial and peripheral nerve blocks provide intraoperative anesthesia, postoperative analgesia (see Chapter 61), treatment of acute pain (e.g., long bone fracture and the pain of acute pancreatitis), and contribute to the management of chronic pain (e.g., headaches, abdominal pain, complex regional pain syndromes [CRPS], and cancer pain). Even though interventional procedures are typically rarely used in nonmalignant chronic pain in children, they are described here so that the pediatrician will understand the different types of procedures that are more commonly carried out in adults and rarely described in pediatric texts. Regional anesthesia provides several benefits: (1) it is an alternative to or augmentation of opioid-based pain control, thereby minimizing the opioid side effects of nausea, vomiting, somnolence, respiratory depression, pruritus, constipation, and physical dependence; (2) it generally provides better quality pain relief because it interrupts nociceptive pathways and more profoundly inhibits endocrine stress responses; (3) it results in earlier ambulation in recovering surgical patients; (4) it helps prevent atelectasis in the setting of severe chest pain; and (5) it usually results in earlier discharge from the hospital. Theoretically, the interruption of nociceptive pathways in the periphery by regional anesthetics will prevent, or reverse the process of amplification of pain signals induced by nociception (CNS wind-up, glial cell activation, etc.). For postoperative pain, effective regional anesthesia and good analgesia reduce the risks of acute pain transitioning into chronic pain.

Regional anesthesia is considered safe and effective if performed by trained staff with the proper equipment. Most nerve blocks are performed by an anesthesiologist or pain management physician; a few are easily performed by a nonanesthesiologist with appropriate training.

Head and Neck Blocks
Primary pain syndromes of the head, such as trigeminal neuralgia, are distinctly unusual in the pediatric population, and few surgical procedures in the head and neck are amenable to regional anesthesia. Pain following tonsillectomy is not amenable to nerve blockade, and neuromuscular incisional pain is usually mitigated by local infiltration of local anesthetic into the wound margins by the surgeon. Headache disorders, very common in the pediatric age group, often respond well to block of the greater and lesser occipital nerves, which provide sensation to much of the cranial structures, from the anterior hairline to the cervical region. The greater occipital nerve can be blocked adjacent to the occipital artery, which can usually be identified at the occipital
ridge midway between the occipital prominence and the mastoid process by palpation, Doppler sound amplification, or visually by ultrasound. The lesser occipital nerves emerge from deeper layers midway between the greater occipital nerve and the mastoid process, where subcutaneous infiltration is effective.

**Upper-Extremity Blocks**

The brachial plexus block controls pain during surgical procedures or other lesions of the upper extremities. This block also protects the extremity from movement, reduces arterial spasm, and blocks sympathetic outflow to the upper extremity. The brachial plexus, responsible for cutaneous and motor innervation of the upper extremity, is an arrangement of nerve fibers originating from spinal nerves C5 through T1, extending from the neck into the axilla, arm, and hand. The brachial plexus innervates the entire upper limb, except for the trapezius muscle and an area of skin near the axilla. If pain is located proximal to the elbow, the brachial plexus may be blocked above the clavicle (roots and trunks); if the pain is located distal to the elbow, the brachial plexus may be blocked below it (cords and nerves). The block may be given as a single injection with a long-acting anesthetic (bupivacaine or ropivacaine, sometimes augmented with clonidine or dexmethasone to prolong block duration and intensity) to provide up to 12 hr of analgesia, or given via a catheter (to infuse local anesthetic) attached to a pump that can provide continuous analgesia over days or even weeks.

Anesthesiologists frequently use an IV regional block (or Bier block) with a local anesthetic in combination with a vasodilator such as phen tolamine and an NSAID (typically ketorolac) to manage the pain of CRPS. The technique requires placement of an IV cannula into the distal part of the affected extremity, exsanguination of the extremity by elevating and wrapping it in an elastic (Esmarch) bandage, and application of a double pneumatic tourniquet, which is then inflated. Local anesthetic with additives as indicated is then injected into the IV cannula, filling the exsanguinated vasculature. The tourniquet must remain inflated for at least 30 min to allow fixation of local anesthetic to tissues, which reduces peak blood concentration and toxicity upon tourniquet deflation. Although the anesthetic effect is limited to the time of tourniquet inflation, analgesia for pain disorders usually persists for days, weeks, or months after the block.

**Trunk and Abdominal Visceral Blocks**

Trunk blocks provide somatic and visceral analgesia and anesthesia for pain or surgery of the thorax and abdominal area. Sympathetic, motor, and sensory blockade may be obtained. These blocks are often used in combination to provide optimal relief. Intercostal and paravertebral blocks may be beneficial in those patients for whom an epidural injection or catheter is contraindicated, for example, in the patient with a coagulopathy. Respiratory function is maintained, and the side effects of opioid therapy are eliminated.

The intercostal, paravertebral, rectus sheath, and transverse abdominal plane blocks are the most useful ones for pediatric chest and abdominal pain. The celiac plexus block is most useful for visceral pain caused by malignant cancer or pancreatitis. A pediatrician may perform an intercostal block, but the other blocks are best performed by an experienced anesthesiologist or pain physician.

The intercostal block is used to block the intercostal nerves, the anterior rami of the thoracic nerves from T1 to T11. These nerve pairs lie inferior and posterior to each rib, and between the inner and innermost intercostal muscles, with their corresponding vein and artery, where they can be blocked, generally posterior to the posterior axillary line. Ultrasound imaging of the intercostal nerves helps avoid injury to intercostal vessels or insertion of the needle through the pleura, which results in pneumothorax.

The paravertebral block, an alternative to intercostal nerve block or epidural analgesia, is useful for pain associated with thoracotomy or with unilateral abdominal surgery, such as nephrectomy or splenectomy. Essentially this block results in multiple intercostal blocks with a single injection. The thoracic paravertebral space, lateral to the vertebral column, contains the sympathetic chain, rami communicantes, and dorsal and ventral roots of the spinal nerves. Because it is a continuous space, local anesthetic injection will provide sensory, motor, and sympathetic blockade to several dermatomes. The paravertebral block may be performed as a single injection, or, for a very prolonged effect, as a continuous infusion over several days or weeks via a catheter inserted in the paravertebral space. This block is best performed by an anesthesiologist or interventional pain physician.

Plexus blocks were once thought to be useful in the diagnosis and treatment of sympathetically mediated pain, CRPS, and other neuropathic pain conditions, but more recently large meta-analyses have shown their utility to be small. The peripheral sympathetic trunk is formed by the branches of the thoracic and lumbar spinal segments,
and it extends from the base of the skull to the coccyx. The sympathetic chain, which consists of separate ganglia containing nerves and autonomic fibers with separate plexuses, can be differentially blocked. These separate plexuses include the stellate ganglion in the lower neck and upper thorax, the celiac plexus in the abdomen, the second lumbar plexus for the lower extremities, and the ganglion impar for the pelvis. When blocks of these plexuses are performed, sympathectomy is obtained without attendant motor or sensory anesthesia.

The stellate ganglion block is indicated for pain in the face or upper extremity as well as for CRPS, phantom limb pain, amputation stump pain, or circulatory insufficiency of the upper extremities. The stellate ganglion arises from spinal nerves C7-T1 and lies anterior to the 1st rib. It contains ganglionic fibers to the head and upper extremities. Structures in close proximity include the subclavian and vertebral arteries anteriorly, the recurrent laryngeal nerve, and the phrenic nerve. The Chassaignac tubercle, the transverse process of the C6 vertebral body superior to the stellate ganglion, is a useful and easily palpable landmark for the block, but radiographic or ultrasound imaging is more typically used than surface anatomy and palpation.

The lumbar sympathetic block addresses pain in the lower extremity, CRPS, phantom limb pain, amputation stump pain, and pain from circulatory insufficiency. The lumbar sympathetic chain contains ganglionic fibers to the pelvis and lower extremities. It lies along the anterolateral surface of the lumbar vertebral bodies and is most often injected between the L2 and L4 vertebral bodies.

The analgesia produced by peripheral sympathetic blocks usually outlives the duration of the local anesthetic, often persisting for weeks or indefinitely. If analgesia is transient, the blocks may be performed with catheter insertion for continuous local anesthesia of the sympathetic chain over a period of days or weeks. Because precise radiographically guided placement of the needle and/or catheter is required for safety and success, sympathetic blocks are generally best performed by an anesthesiologist, interventional pain physician, or interventional radiologist.

**Epidural Anesthesia (Thoracic, Lumbar, and Caudal)**

Epidural anesthesia and analgesia are indicated for pain below the clavicles, management of CRPS, cancer pain unresponsive to systemic opioids, and pain limited by opioid side effects.

The 3 layers of the spinal meninges—the dura mater (outer), the arachnoid mater (middle), and the pia mater (inner)—envelop the spinal neural tissue. The subarachnoid space contains cerebrospinal fluid between the arachnoid mater and pia mater. The epidural space extends from the foramen magnum to the sacral hiatus. The epidural space, which contains fat, lymphatics, blood vessels, and the spinal nerves as they leave the spinal cord, separates the dura mater from the perivascular sheath surrounding vertebral bodies. In children, the fat in the epidural space is not as dense as in adults, predisposing to greater spread of the local anesthetic from the site of injection.

Epidural local anesthetics block both sensory and sympathetic fibers, and if the local anesthetic is of sufficient concentration, they also block motor fibers. Mild hypotension may occur, although it is unusual in children younger than 8 yr. Epidural local anesthetics high in the thoracic spine may also anesthetize the sympathetic nerves to the heart (the cardiac accelerator fibers), producing bradycardia. In addition to using local anesthetics, it is routine to use opioids and α-agonists in the epidural space. These agents have their primary site of action in the spinal cord, to which they diffuse from their epidural depot. Side effects of epidural opioid administration include delayed respiratory depression, particularly when hydrophilic opioids such as morphine are used. The risk of this effect requires that children receiving epidural opioids by intermittent injection or continuous infusion be monitored by continuous pulse oximetry and nursing observation, particularly during the 1st 24 hr of therapy or after significant dose escalations. Respiratory depression occurring after the 1st 24 hr of epidural opioid administration is distinctly unusual.

Epidural clonidine, an α2-agonist with μ-opioid analgesic properties, is associated with minimal risk and side effects. Although product labeling indicates use only in children with severe cancer pain, it is commonly used for routine postoperative pain as well as pain syndromes such as CRPS. Mild sedation is the most common side effect of epidural clonidine, and it is not associated with respiratory depression.

Because performing epidural blockade is technical and may result in spinal cord injury, it is best done by an anesthesiologist or pain physician skilled in the technique.

**INTRATECHAL ANALGESIA**

Intrathecal catheters infused with opioids, clonidine, ziconotide, and local anesthetics are occasionally applicable in pediatric patients suffering from intractable pain from cancer or other conditions. Typically, intrathecal catheters are attached to an implanted electronic pump containing a drug reservoir sufficient for several months of dosing. The technique is technical and best performed by an experienced pain management physician.

**NERVE ABLATION AND DESTRUCTION**

In infrequent pediatric cases, pain remains refractory in spite of maximal reliance upon oral and IV medications and nerve blockade. In these instances, temporary (ablation) or permanent (lytic) destruction of 1 or more nerves may be performed. These situations are rather extraordinary in children, and the techniques should be carefully weighed against the consideration of inducing permanent nerve destruction in a growing child with decades of life ahead. On the other hand, when pain is severe in life-limiting disease processes, the long-term considerations are less concerning, and these techniques should be discussed with a pain management specialist skilled in their performance.

**CONSIDERATIONS FOR SPECIAL PEDIATRIC POPULATIONS**

**Pain Perception and Effects of Pain on Newborns and Infants**

There are a number of sources of pain in the newborn period. These include acute pain (diagnostic and therapeutic procedures, minor surgery, monitoring), continuous pain (pain from thermal/chemical burns, postsurgical and inflammatory pain), and chronic or disease-related pain (repeated heelsticks, indwelling catheters, necrotizing enterocolitis, nerve injury, chronic conditions, thrombophlebitis). The most common sources of pain in healthy infants are acute procedures, such as heel lances, operations, and, in boys, circumcision.

In premature infants in the neonatal intensive care unit (NICU), there are many procedures performed. In the 1st wk of life, approximately 94% of preterm infants younger than 28 wk of gestational age are ventilated. Other procedures are heelsticks (the most commonly performed) and airway suctioning. Only a few of these procedures are preceded by any type of analgesia. Repeated handling and acute pain episodes sensitize the neonate to increased reactivity and stress responses to subsequent procedures they undergo as neonates or children. Typical stress responses include increases in heart rate, respiratory rate, blood pressure, and intracranial pressure. Cardiac vagal tone, transcutaneous oxygen saturation, carbon dioxide levels, and peripheral blood flow are decreased. Autonomic signs include changes in skin color, vomiting, gagging, hiccupping, diaphoresis, dilated pupils, and palmar and forehead sweating.

To assess pain in the newborn, it is critical to observe the infant for facial expression, body movements, crying, and any other atypical functional behaviors. The observer must consider the context in which the behavior is experienced. The infant’s state (agitated, alert, asleep) and gestational and post-gestational ages also affect behavioral stress responses.

Untreated pain in the newborn has serious short-term and longer-term consequences. There has been a shift in most NICUs to more liberal use of opioids. Nonetheless, morphine, the traditional gold standard of analgesia for acute pain, may not be very effective and may have adverse long-term consequences. No differences have been found in the incidence of severe intraventricular hemorrhage or in the mortality rate when infants receiving morphine are compared with the
placebo group, and there are no changes in assessed pain from tracheal suctioning in ventilated infants receiving morphine compared with those receiving a placebo infusion. Morphine may not alleviate acute pain in ventilated preterm neonates, although there are few data on the effects of morphine and fentanyl in nonventilated newborns. The lack of opioid effects for acute pain in neonates may be due to an immaturity of opioid receptors; acute pain may cause the uncoupling of μ opioid receptors in the forebrain. Repetitive acute pain may create central neural changes in the newborn that may have long-term consequences for later pain vulnerability, cognitive effects, and opioid tolerance. There are both anatomic and behavioral manifestations of the adverse effects of neonatal stress, including pain, on brain development. Most neonatologists use opioids in painful situations. Sucrose and pacifiers are also being used in the NICU. The effects of sucrose (sweet taste) are believed to be opioid-mediated because they are reversed with naloxone; stress and pain relief are integrated through the endogenous opioid system. Sucrose, with or without a pacifier, may be effective for acute pain and stress control. Other nonpharmacologic strategies for stress and pain control include infant care by an individual primary nurse, tactile-kinesthetic stimuli (massage), “kangaroo care,” and soothing sensorial saturation.

**Children with Cancer Pain**

The World Health Organization proposed an analgesic therapy model for cancer pain known as the *analgesic ladder* (Table 62-11). Designed to guide therapy in the Third World, this ladder consists of a hierarchy of oral pharmacologic interventions intended to treat pain increasing in magnitude. The hierarchy ignores modalities such as the use of nonconventional analgesics and interventional pain procedures, which are within the capability of physicians to prescribe in developed countries. Nevertheless, because oral medications are simple and efficacious, especially for home use, the ladder presents a framework for rationally using them before applying other drugs and techniques of drug administration.

Oral medications are the 1st line of analgesic treatment. Because NSAIDs affect platelet adherence, they are typically not used. Opioid therapy is the preferred approach for moderate or severe pain. Nonopioid analgesics are used for mild pain, a weak opioid is added for moderate pain, and strong opioids are administered for more severe pain. Adjuvant analgesics can be added, and side effects and comorbid symptoms are actively managed. Determining the type and sources of the pain will help develop an effective analgesic plan. Certain treatments, such as the chemotherapeutic agent vincristine, are associated with neuropathic pain. Such pain might require anticonvulsants or TCAs. Organ-stretching pain from tumor growth within an organ might require strong opioids and/or radiation therapy if the tumor is radiosensitive. Organ obstruction, such as intestinal obstruction, should be diagnosed to relieve or bypass the obstruction.

It is important to consider both pharmacologic and nonpharmacologic strategies (e.g., cognitive-behavioral treatment, family and parent support) to treat pain in children with cancer.

**Children with Pain Associated with Advanced Disease**

Patients with advanced diseases, including cancer, AIDS, neurodegenerative disorders, and cystic fibrosis, need palliative care approaches that focus on optimal quality of life. Nonpharmacologic and pharmacologic means of management of pain and other distressing symptoms are palliative care’s key components. It should be highlighted here that “palliative care” should be offered to all children with serious diseases, whether or not the diseases are potentially curable and whether or not long life expectancy is predicted. Examples include young children diagnosed with acute lymphoblastic leukemia (>90% posttreatment life expectancy) and children undergoing organ transplantation. Palliative care in pediatrics is meant to connote treatment that focuses on symptom reduction, quality of life, and good family and clinical team communication. It is not just reserved for patients in hospice care or those at the end of life. Differences among these conditions that relate to the progression of underlying illness, associated distressing symptoms, and common emotional responses should shape individual treatment plans (see Chapter 43). For end-of-life care, more than 90% of children and adolescents with cancer can be made comfortable by standard escalation of opioids according to the World Health Organization protocol. A small subgroup (5%) has enormous opioid dose escalation to >100 times the standard morphine or other opiate infusion rate. In most of these cases, there is spread of solid tumors to the spinal cord, roots, or plexus, and signs of neuropathic pain are evident. Methadone given orally is often used in palliative care, not just end of life care, because of its long half-life and its targeting of both opioid and N-methyl-D-aspartate receptors. The type of pain experienced by the patient (neuropathic, myofacial) should determine the need for adjunctive agents. Complementary measures, such as massage, hypnotherapy, and/or spiritual care, should also be considered in palliative care. Although the oral route of opioid administration should be encouraged, especially to facilitate care at home if possible, some children are unable to take oral opioids. Transdermal and sublingual routes, as well as an intravenous infusion with a PCA, are likely next choices. Small, portable infusion pumps are convenient for home use. If venous access is limited, a useful alternative is to administer opioids (especially morphine or hydromorphone, but not methadone or meperidine) through continuous subcutaneous infusion, with or without a bolus option. A small (e.g., 22-gauge) cannula is placed under the skin and secured on the thorax, abdomen, or thigh. Sites may be changed every 3–7 days, as needed. As noted, alternative routes for opioids include the transdermal and oral transmucosal routes. These latter routes are preferred over IV and subcutaneous drug delivery when the patient is being treated at home.

**Examples of Chronic and Recurrent Pain Syndromes**

Chronic pain is defined as recurrent or persistent pain lasting longer than the normal tissue healing time, approximately 3–6 mo. Children may experience pain related to injury (e.g., burns) or a chronic or underlying disease process (e.g., cancer, arthritis); pain can also be the chronic condition itself (e.g., CRPS, fibromyalgia, functional abdominal pain). During childhood, abdominal, musculoskeletal, and headache pain are the most frequently occurring conditions. However, definitions of chronic pain do not take into account standard criteria for assessing particular pain symptoms or for evaluating the intensity or impact of pain, and therefore include individuals with varying symptoms and experiences. Consequently, in epidemiologic surveys, prevalence estimates vary widely. Overall prevalence rates for different childhood pains range from 4–88%. For example, an average of 13.5–31.8% of adolescents in a community sample reported having weekly abdominal, headache, or musculoskeletal pains. Most epidemiologic studies report prevalence and do not report the severity or impact of the pain. Research indicates that only a subset of children and adolescents with chronic pain (approximately 5%) experience moderate-severe disability, and this likely better represents the estimated population for whom help is needed to treat pain and associated problems.
COMPLEX REGIONAL PAIN SYNDROMES

Neuropathic pain is caused by abnormal excitability in the peripheral or CNS that may persist after an injury heals or inflammation subsides. The pain, which can be acute or chronic, is described as burning or stabbing and may be associated with cutaneous hypersensitivity (allodynia), distortion of sensation (dysesthesia), and amplification of nocuous sensations (hyperalgesia and hyperpathia). Neuropathic pain conditions may be responsible for >35% of referrals to chronic pain clinics, conditions that commonly include posttraumatic and posturgical peripheral nerve injuries, phantom pain after amputation, pain after spinal cord injury, and pain caused by metabolic neuropathies. Neuropathic pain typically responds poorly to opioids. In adults, evidence suggests the efficacy of TCAs (nortriptyline, amitriptyline) and anticonvulsants (gabapentin, pregabalin) for treatment of neuropathic pain (see Tables 62-9 and 62-10).

CRPS type 1, formerly known as reflex sympathetic dystrophy, is well-described in the pediatric population. CRPS type 1 is a syndrome of neuropathic pain that typically follows an antecedent and usually minor injury to an extremity without identifiable nerve injury. The syndrome of CRPS type 1 includes severe spontaneous neuropathic pain, hyperpathia, hyperalgesia, severe cutaneous allodynia to touch and cold, changes in blood flow (typically extremity cyanosis), and sweating. In more advanced cases, symptoms include dystrophic changes of the hair, nails, and skin, immobility of the extremity (dystonia), and muscle atrophy. In the most advanced cases, symptoms include ankylosis of the joints of the extremity. Specific causal factors in CRPS type 1 in both children and adults remain elusive, although coincidental events may be noted. CRPS type 2, formerly referred to as causalgia, is less common.

The syndromes of CRPS type 2 and CRPS type 1 are virtually identical, except that the former is associated with a well-defined peripheral nerve injury. Treatment of CRPS in children has been extrapolated from that in adults, with some low-level evidence for efficacy of physical therapy, cognitive-behavioral therapy, nerve blocks, TCAs, gabapentin, and some other related drugs. All experts in pediatric pain management agree on the value of aggressive physical therapy. Some centers provide aggressive therapy without the use of pharmacologic agents or Interventional nerve blocks; unfortunately, recurrent episodes may be seen in up to 50% of patients. Physical therapy can be extraordinarily painful for children to endure; it is tolerated only by the most stoic and motivated patients. If children have difficulty enduring the pain, there is a well-established role for using pharmacologic agents with or without peripheral or central neuraxial nerve blocks to render the affected limb sufficiently analgesic so that physical therapy can be tolerated. Pharmacologic interventions include the use of AEDs such as gabapentin and/or TCAs such as amitriptyline (see Fig. 62-4). Although there is clear evidence of a peripheral inflammatory component of CRPS, with release of cytokines and other inflammatory mediators from the peripheral nervous system in the affected limb, the use of antiinflammatory agents has been disappointing.

Commonly used nerve block techniques include sympathetic nerve blocks, IV regional anesthetics, epidural analgesia, and peripheral nerve blocks. In extreme and refractory cases, more invasive strategies have been reported, including surgical sympathectomy and spinal cord stimulation. Although an array of treatments have some benefit, the mainstay of treatment remains physical therapy emphasizing desensitization, strengthening, and functional improvement. Additionally, pharmacologic agents and psychologic and complementary therapies are important components of a treatment plan. Invasive techniques, although not curative, are valuable if they permit the performance of frequent and aggressive physical therapy that cannot be carried out otherwise. Some children with CRPS become so easily sensitized that persistent and bothersome pain may develop at the site of the invasive procedure. A good biopsychosocial evaluation will help determine the orientation of the treatment components. At this time, there are insufficient data to indicate the superior value of Interventional blocks, such as epidural anesthesia delivery, in children with CRPS type 1, over physical and psychologic interventions, with or without pharmacologic support.

MYOFASCIAL PAIN DISORDERS AND FIBROMYALGIA

Myofascial pain disorders are associated with tender points in the affected muscles as well as with muscle spasms (tight muscles). Treatment is targeted at relaxing the affected muscles through physical therapy, yoga, massage, and/or acupuncture. Rarely are pharmacologic muscle relaxants helpful other than for creating tiredness at night for sleep. Dry needling or injections of local anesthetic into the tender points has been advocated, but the data do not support this as a standard treatment. Similarly, although botulinum toxin injections may be used, no data support this practice in children. Often poor body postures, repetitive use of a part of the body not used to that movement, or carrying heavy backpacks initiates pain. When it becomes widespread with multiple tender points, the diagnosis may be made of juvenile fibromyalgia, which may or may not continue to subsequently become adult fibromyalgia. Likely there are different subtypes of widespread pain syndromes, and physical therapy is a key component of treatment. Psychologic interventions may play an important role to assist the child in resuming normal activities and to manage any psychologic comorbidities. Any pain rehabilitation plan should enhance return to full function. Because there is a high incidence of chronic pain in parents of children presenting with a chronic pain condition, especially fibromyalgia, attention to parent and family factors is important. Parent training may entail teaching the parent to model more appropriate pain coping behaviors and to recognize the child’s independent attempts to manage pain and function adaptively. Parents may also need referrals to obtain appropriate pain management for their own pain condition.

The drugs pregabalin and duloxetine have both been approved for management of fibromyalgia in adults in the United States, but there are no clinical studies confirming their effectiveness in children and adolescents.

ERYTHROMELALGIA

Erythromelalgia in children is generally primary, whereas in adults it may be either primary or secondary to malignancy or other hematologic disorders such as polycythemia vera. Patients with this disorder exhibit red, warm, hyperperfused distal limbs. The disorder is usually bilateral, and it may involve either or both the hands and feet. Patients perceive burning pain and typically seek relief by immersing the affected extremities in ice water, sometimes so often and for so long so that skin pathology results. Primary erythromelalgia has recently been shown to be caused by a genetic mutation in the gene for the NaV1.7 neuronal sodium channel on peripheral C nociceptive fibers, resulting in their spontaneous depolarization, and thus continuous burning pain. The most common mutation identified is in the SCN9A gene, although there are several mutations that affect the NaV1.7 channel. Interestingly, another mutation in the NaV1.7 channel results in a rare but devastating genetic condition, the congenital indifference to pain.

It is easy to distinguish erythromelalgia (or related syndromes) from CRPS. The limb afflicted with CRPS is typically cold and cyanotic, the disease is typically unilateral, and children with CRPS have cold alloodynia, making immersion in cold water exquisitely painful; in erythromelalgia, ice water immersion is analgesic, the condition is bilateral and symmetrical, and associated with hyperperfusion of the distal extremity. The evaluation of hyperperfused limbs with burning pain should include genetic testing for Fabry disease and screening for hematologic malignancies, with diagnosis of primary erythromelalgia being one of exclusion. There are presently few clinical laboratories that are certified to perform the DNA analysis required to identify the common NaV1.7 mutations.

The definitive treatment of Fabry disease includes enzyme replacement as disease-modifying treatment and administration of neurophathic pain medications, such as gabapentin, although the success of antineuropathic pain drugs in small-fiber neuropathies has not been impressive. The treatment of erythromelalgia is far more problematic. Antineuropathic pain medications, such as AEDs and TCAs are typically prescribed but rarely helpful (see Fig. 62-4). Although one might predict that sodium channel–blocking AEDs might be effective in this
sodium channelopathy, oxcarbazepine has not proven to be a particularly effective modality. The pain responds well to regional anesthetic nerve blocks, but it returns immediately when the effects of the nerve block resolve. In contrast, in other neuropathic syndromes, the analgesia usually (and inexplicably) persists well after the resolution of the pharmacologic nerve block. Aspirin and even nitroprusside infusions are reported to be of benefit with secondary erythromelalgia, but they are not reported to be helpful in children with primary erythromelalgia. There are case reports in adults and clinical experience in children suggesting that periodic treatment with high-dose capsaicin cream is effective in alleviating the burning pain and disability of erythromelalgia. Capsaicin (essence of chili pepper) cream is a vanilloid receptor (TRPV1) agonist that depletes small-fiber peripheral nerve endings of the neurotransmitter substance P, which is an important neurotransmitter in the generation and transmission of nociceptive impulses. Once depleted, these nerve endings are no longer capable of generating spontaneous pain until the receptors regenerate, a process that takes many months.

OTHER CHRONIC PAIN CONDITIONS IN CHILDREN

It should be noted that there are a variety of genetic and other medical/surgical conditions that are often associated with chronic pain. Examples include Fabry disease, Chiari/syringomyelia, juvenile idiopathic arthritis, mitochondrial disorders, degenerative neurologic diseases, cerebral palsy, autism spectrum disorders, intestinal pseudoobstruction, inflammatory bowel disease, chronic migraine and chronic daily headaches, irritable bowel disease, and others. In many cases, treating the underlying disease, such as enzyme replacement in Fabry disease and in other lysosomal disorders, will reduce what otherwise might be progression of symptoms, but may not totally reduce pain and suffering, and other modalities will be needed. Finally, pain that persists and is not well treated can lead to central sensitization and widespread pain, such as seen in children with one pain source who develop fibromyalgia.

MANAGING COMPLEX CHRONIC PAIN PROBLEMS

Some patients with chronic pain have a prolonged course of evaluation in attempts to find what is expected as the singular “cause” of the pain, and thus also undergo many failed treatments. Parents worry that the doctors have not yet discovered the cause that may be serious and life-threatening, and children often feel not believed, that they are faking their pain, or are “crazy.” There may be no identifiable or diagnosable condition and families may seek opinions from multiple treatment facilities in an attempt to find help for their suffering child. In fact, in many cases, what may have begun as an acute injury or infectious event may result for some children into a chronic pain syndrome, with changes in the neurobiology of the pain signaling system.

In the context of disabling chronic pain, it is very important for the pediatrician to (1) avoid overmedication because this can exacerbate associated disability, (2) maintain an open mind and reassess the diagnosis if the clinical presentation changes, and (3) understand and communicate to the family that pain has a biologic basis (likely related to neural signaling and neurotransmitter dysregulation), and the pain is naturally distressing to the child and family. All patients and families should receive a simple explanation of pain physiology that helps them understand the importance of (1) functional rehabilitation to normalize pain signaling, (2) the low risk of causing further injury with systematic increases in normal functioning, and (3) the likely failure of treatment if pain is managed as if it were acute. Because it is counter-intuitive for most people to move a part of the body that hurts, many patients with chronic pain have atrophy or contractures of a painful extremity from disuse. Additionally, associated increases in worry and anxiety may exacerbate pain and leave the body even more vulnerable to further illness, injury, and disability. Pain can have a significant impact on many areas of normal functioning and routine for children, and school absenteeism and related consequences of missed schooling are often significant problems. Appropriate assessment and evaluation of the child with chronic pain and the child’s family is the critical first step necessary in developing a treatment plan.

Interdisciplinary pediatric pain programs have become the standard of care for treating complex chronic pain problems in youth. In recognition of the severity and complexity of pain and disability for some children, different settings and treatment delivery models for providing pain care have been explored. One option is inpatient and day hospital treatment programs. They often address barriers to access to outpatient treatment and coordination of care. In addition, they provide an intensive treatment option for children who do not make adequate progress in outpatient treatment or who are severely disabled by pain. Early programs developed in the 1990s focused on treatment of CRPS through intensive inpatient rehabilitation and exercise-based treatment programs. Later developing programs expanded to other clinical populations and expanded the treatment focus to incorporate a range of rehabilitation and psychologic therapies delivered both individually and in groups. The typical length of inpatient admissions for children with chronic pain in such programs is 3-4 wk and there is emerging evidence to suggest benefit from these programs.

Another intervention delivery option is remote management, referring to pain interventions utilized outside of the clinic/hospital setting to reach children in their homes or communities. Interventions are typically delivered using some form of technology, such as the Internet, or rely on other media such as telephone counseling or use of written self-help materials. Most typically, remote management of pain includes monitoring, counseling, and/or delivery of behavioral and CBT interventions. Internet interventions have received the most research attention to date with published examples for several different pediatric chronic pain conditions with promising findings for pain reduction. Telemedicine, while in widespread use clinically for many pediatric health conditions, has not yet been formally evaluated in pediatric pain. Within any community, the pediatrician will need to locate appropriate referral sources for patients with complex chronic pain.

Bibliography is available at Expert Consult.
Poisoning is now the number 1 cause of injury death in the United States, even surpassing that from motor vehicle collisions. The majority of these deaths are unintentional (i.e., not suicide). In adolescents, poisoning is the third leading cause of injury-related death. Of the more than 2 million human poisoning exposures reported annually to the National Poison Data Systems of the American Association of Poison Control Centers, approximately 50% occur in children younger than 6 yr old. Almost all of these exposures are unintentional and reflect the propensity for young children to put virtually anything in their mouths. Fortunately, children younger than 6 yr account for <2% of all poisoning fatalities reported to National Poison Data Systems.

More than 90% of toxic exposures in children occur in the home, and most involve only a single substance. Ingestion accounts for the vast majority of exposures, with a minority occurring via the dermal, inhalational, and ophthalmic routes. Approximately 50% of cases involve nondrug substances, such as cosmetics, personal care items, cleaning solutions, plants, and foreign bodies. Pharmaceutical preparations account for the remainder of exposures, and analgesics, topical preparations, cough and cold products, and vitamins are the most commonly reported categories.

The majority of poisoning exposures in children younger than 6 yr can be managed without direct medical intervention (beyond a call to

*Small dose* typically implies 1 or 2 pills or 5 mL. CNS, central nervous system.

the regional poison control center), either because the product involved is not inherently toxic or the quantity of the material involved is not sufficient to produce clinically relevant toxic effects. However, a number of substances are potentially highly toxic to toddlers in small doses (Table 63-1). In 2012, carbon monoxide and analgesics (acetaminophen and salicylate) were the leading causes of poisoning fatalities in young children (<6 yr). In addition, prescription opioids, antidepressants, cardiovascular drugs, and aliphatic hydrocarbons were significant causes of mortality.

Poison prevention education should be an integral part of all well-child visits, starting at the 6 mo visit. Counseling parents and other caregivers about potential poisoning risks, how to poison-proof a child's environment, and what to do if an ingestion or exposure occurs diminishes the likelihood of serious morbidity or mortality. Poison prevention education materials are available from the American Academy of Pediatrics and regional poison control centers. A network of poison control centers exists in the United States, and anyone at any time can contact a regional poison center by calling this toll-free number: 1-800-222-1222. Parents should be encouraged to share this number with grandparents, relatives, babysitters, and any other caregivers.

Product safety measures, poison prevention education, early recognition of exposures, and around-the-clock access to regionally based poison control centers all contribute to the favorable outcomes in young children. Poisoning exposures in children 6-12 yr old are much less common, involving only approximately 6% of all reported pediatric exposures. A second peak in pediatric exposures occurs in adolescence. Exposures in the adolescent age group are primarily intentional (suicide or abuse or misuse of substances) and thus often result in more severe toxicity (see Chapter 114). Families should be informed and given anticipatory guidance that nonprescription and prescription medications, and even household products (e.g., inhalants), are common sources of adolescent exposures. Adolescents (ages 13-19 yr) accounted for 45 of the 73 poison-related pediatric deaths in 2012 reported to National Poison Data System (4% of all fatalities called in to poison centers). Pediatricians should be aware of the signs of drug abuse or suicidal ideation in this population and should aggressively intervene (see Chapter 114).

**PREVENTION**

Deaths caused by unintentional poisoning among younger children have decreased dramatically over the past 2 decades, particularly among children younger than 5 yr of age. In 1970, when the Poison Packaging Prevention Act was passed, 226 poisoning deaths of children younger than 5 yr occurred compared with only 21 in 2012. Poisoning prevention demonstrates the effectiveness of passive strategies, including the use of child-resistant packaging and limited doses per container. Difficulty using child-resistant containers by adults is an important cause of poisoning in young children today; in 18.5% of households in which poisoning occurred in children younger than 5 yr of age, the child-resistant closure was replaced, and 65% of the packaging used did not work properly. Nearly 20% of ingestions occur from drugs owned by grandparents, a group that has difficulty using traditional child-resistant containers.

Even though there has been success in preventing poisoning in young children, there has been a remarkable rise in poison-related death over the past 20 yr in the adolescent population. This has mirrored the ever-increasing rate of opioid prescriptions written by healthcare providers.

**APPROACH TO THE POISONED PATIENT**

The initial approach to the patient with a witnessed or suspected poisoning should be no different than that in any other sick child, starting with stabilization and rapid assessment of the airway, breathing, circulation, and mental status (see Chapter 67). In any patient with altered mental status, a serum dextrose concentration should be obtained early and naloxone administration should be considered. A targeted history and physical examination serves as the foundation for a thoughtful differential diagnosis, which can then be further refined through laboratory testing and other diagnostic studies.

**INITIAL EVALUATION**

**History**

Obtaining an accurate problem-oriented history is of paramount importance. Intentional poisonings (suicide attempts; abuse or misuse) are typically more severe than unintentional, exploratory ingestions. In patients without a witnessed exposure, historical features such as age of the child (toddler or adolescent), acute onset of symptoms without prodrome, sudden alteration of mental status, multiple system organ dysfunction, or high levels of household stress should suggest a possible diagnosis of poisoning.

**Description of the Exposure**

For household and workplace products, names (brand, generic, chemical) and specific ingredients, along with their concentrations, can often...
be obtained from the labels. Poison control center specialists can also help to identify possible ingredients and review the potential toxicities of each component. In cases of suspected ingestion, poison center specialists can help identify pills based on markings, shape, and color. If referred to the hospital for evaluation, parents should be instructed to bring the products, pills, and/or containers with them to assist with identifying and quantifying the exposure. If a child is found with an unknown pill in the child’s mouth, the history must include a list of all medications in the child’s environment (including medications that grandparents, parents, siblings, caregivers, or other visitors might have brought into the house). In the case of an unknown exposure, clarifying where the child was found (e.g., garage, kitchen, laundry room, bathroom, backyard, workplace) can help to generate a list of potential toxins.

Next, it is important to clarify the timing of the ingestion and to obtain some estimate of how much of the substance was ingested. It is better to overestimate the amount ingested to prepare for the worst-case scenario. Counting pills or measuring the remaining volume of a liquid ingested can sometimes be useful in generating estimates. For inhalational, ocular, or dermal exposures, the concentration of the agent and the length of contact time with the material should be determined if possible.

Symptoms
Obtaining a description of symptoms experienced after ingestion, including their timing of onset relative to the time of ingestion and their progression, can generate a list of potential toxins and to predict the severity of the ingestion. Coupled with physical exam findings, reported symptoms assist practitioners in identifying toxidromes or recognized poisoning syndromes suggestive of poisoning from specific substances or classes of substances (Tables 63-2, 63-3, and 63-4).

Past Medical History
Underlying diseases can make a child more susceptible to the effects of a toxin. Concurrent drug therapy can also increase susceptibility because certain drugs may interact with the toxin. Pregnancy is a common precipitating factor in adolescents’ suicide attempts and can influence both evaluation of the patient and subsequent treatment. A history of psychiatric illness can make patients more prone to substance abuse, misuse, intentional ingestions, and polypharmacy complications. A developmental history is important to ensure that the history provided is appropriate for the child’s developmental stage (e.g., a report of a 6 mo old picking up a large container of laundry detergent and drinking it should raise a red flag).

Social History
Understanding the child’s social environment helps to identify potential sources of exposures (caregivers, visitors, grandparents, recent parties or social gatherings) and environmental stressors (new baby, parent’s illness, financial stress) that might have contributed to the ingestion. Unfortunately, some poisonings occur in the setting of serious neglect or intentional abuse.

Physical Examination
A targeted physical exam is important to identifying the potential toxin and assessing the severity of the exposure. Initial efforts should be directed toward assessing and stabilizing the airway, breathing, circulation, and mental status. Once one has ensured that the airway is secure and the patient is stable from a cardiopulmonary standpoint, a more extensive physical exam can help to identify characteristics of specific toxins or classes of toxins.

In the poisoned patient, the key features of the physical exam are the vital signs, mental status, pupils (size, reactivity) nystagmus, skin, bowel sounds, and odors. These findings might suggest a toxidrome that can guide the differential diagnosis and initial management.

Laboratory Evaluation
For select intoxications (e.g., salicylates, some anticonvulsants, acetaminophen, iron, digoxin, methanol, lithium, ethylene glycol, carbon monoxide, lead), quantitative blood concentrations are integral to confirming the diagnosis and formulating a treatment plan. For most exposures, quantitative measurement is not readily available and is not likely to alter management. All intoxicant levels must be interpreted in conjunction with the history. For instance, a methanol level of 20 mg/dL 1 hr after ingestion may well be nontoxic, whereas a similar level 24 hr after ingestion implies a patient with significant poisoning. In general, patients with multiple or chronic exposures to a drug or other chemical will be more symptomatic at lower drug levels than those with a single exposure.

Both urine drug-of-abuse screens and the more comprehensive drug screens vary widely in their ability to detect toxins and generally add little information to the clinical assessment, particularly if the agent is known and the patient’s symptoms are consistent with that agent. If a drug screen is ordered, it is important to know that the components screened for, and the lower limits of detection, vary from laboratory to laboratory. In addition, the interpretation of most drug screens is hampered by false-positive and false-negative results; standard urine opiate screens will not be positive after exposure to a synthetic opioid (e.g., methadone, buprenorphine, fentanyl). The urine drug-of-abuse screen is typically of limited utility when it comes to medical clearance, but does serve a useful function for psychiatrists in their evaluation of the adolescent patient. Apart from its psychiatric usefulness, urine drug-of-abuse screens are potentially helpful in patients with altered mental status of unknown etiology, persistent, unexplained tachycardia, acute myocardial ischemia or stroke at a young age, and in the assessment of a neglected or abused child. Consultation with a medical toxicologist can be helpful in interpreting drug screens and ordering specific drug levels or metabolites that can aid in patient management.

In the case of a neglected or allegedly abused child, a positive toxicology screen can add substantial weight to a claim of abuse or neglect. In these cases and any case with medicolegal implications, any positive screen must be confirmed with gas chromatography/mass spectrometry, which is considered the gold standard measurement for legal purposes.

Acetaminophen is a widely available medication and a commonly detected coingestant with the potential for severe toxicity. There is an effective antidote to acetaminophen poisoning that is time-dependent. Given that patients might initially be asymptomatic and might not report acetaminophen as a coingestant, an acetaminophen level should be checked in all patients who present after an intentional exposure or ingestion. A basic chemistry panel (electrolytes, renal function, glucose) is necessary for all poisoned or potentially poisoned patients. Any patient with acidosis (a low serum bicarbonate level on the serum chemistry panel) must have an anion gap calculated because of the more specific differential diagnoses associated with an elevated anion gap metabolic acidosis. Patients with a known overdose of acetaminophen should have their liver transaminases assessed, as well as an INR (international normalized ratio). A serum creatine kinase level is indicated on any patient with a prolonged “down time” as rhabdomyolysis can result from laying supine on a hard surface without movement for just a few hours. Serum osmolality is only helpful as a surrogate marker for a toxic alcohol exposure if a serum concentration of the alcohol cannot be obtained in a reasonable time frame. A urine pregnancy test is, of course, mandatory for all adolescent female patients. Based on the clinical presentation and the presumed poison, additional lab tests may also be helpful (Table 63-5).

Additional Diagnostic Testing
An electrocardiogram (ECG) is a quick and noninvasive bedside test that can yield important clues to diagnosis and prognosis. Toxicologists pay particular attention to the ECG intervals (Table 63-6). A widened QRS interval, putting the patient at risk for monomorphic ventricular tachycardia, suggests blockade of fast sodium channels, and may be seen after ingestion of tricyclic antidepressants, diphenhydramine, and cocaine, among others. A widened QTc interval suggests effects at the potassium rectifier channels and portends a risk of torsades de pointes (polymorphic ventricular tachycardia).

GHB, γ-hydroxybutyrate; LSD, lysergic acid diethylamide; NSAID, nonsteroidal antiinflammatory drug; PCP, phencyclidine; TCA, tricyclic antidepressant.

Chest x-ray may reveal signs of pneumonitis (e.g., hydrocarbon aspiration), noncardiogenic pulmonary edema (e.g., salicylate toxicity), or a foreign body. Abdominal x-ray is most helpful in screening for the presence of lead paint chips or other foreign bodies. It may detect a bezoar, demonstrate radiopaque tablets, or reveal drug packets in a body packer. Upper endoscopy may be useful for prognosis after significant caustic ingestions. Further diagnostic testing is based on the differential diagnosis and pattern of presentation.

**PRINCIPLES OF MANAGEMENT**

The principles of management of the poisoned patient are supportive care, antidotes, decontamination, and enhanced elimination. Few patients meet criteria for all of these interventions, though clinicians should consider each option in every poisoned patient so as not to miss a potentially lifesaving therapy. Antidotes are available for relatively few poisons (Table 63-7), thus emphasizing the importance of meticulous supportive care and close clinical monitoring.

Poison control center staff are specifically trained to provide expertise in the management of poisoning exposures. Parents should be instructed to call the poison control center (1-800-222-1222) for any concerning exposure. Poison specialists can assist parents in assessing the potential toxicity and severity of the exposure; they can further determine which children can be safely monitored at home and which children should be referred to the emergency department for further evaluation.

evaluation and care. Ninety percent of all exposures in children younger than 6 yr of age called into poison centers are managed at home. The American Academy of Clinical Toxicology has generated consensus statements for out-of-hospital management of common ingestions (e.g., acetaminophen, iron, calcium channel blockers) that serve to guide poison center recommendations regarding whom to refer to an emergency department. Up to a third of calls to poison centers involve hospitalized patients.

### SUPPORTIVE CARE

Careful attention is paid first to the “ABCs” of airway, breathing and circulation; there should be a low threshold to aggressively manage the airway of a poisoned patient because of the patient’s propensity to

</table>
quickly become comatose. In fact, endotracheal intubation is often the only significant intervention needed in many poisoned patients, especially those poisoned with neuroleptics. An important caveat is with the tachypneic patient with a clear lung exam and normal oxygen saturation. This should alert the clinician to the likelihood that the patient is compensating for an acidemia. Paralyzing such a patient and ventilating them might prove fatal. If intubation is absolutely necessary for airway protection or a tiring patient, a good rule of thumb is to match the ventilatory settings to the patient’s preintubation minute ventilation.

In the hypotensive patient, it should be remembered that these patients often are not hypovolemic, but are poisoned; aggressive fluid resuscitation may lead to fluid overload. If hypotension persists after 1 or 2 standard boluses of crystalloid, infusion of a direct-acting vasoconstrictor, such as norepinephrine or epinephrine, is preferred. Dysrhythmias are managed in the standard fashion apart from those caused by agents that block the fast sodium channels of the heart for which sodium bicarbonate therapy is utilized.

Seizures are primarily managed with agents that potentiate the γ-aminobutyric acid complex, such as benzodiazepines or barbiturates. Creatinine kinase levels should be drawn on any patient found unconscious. The goal of supportive therapy is to support the patient’s vital functions until the patient can eliminate the toxin.

### Antidotes

Antidotes are available for relatively few toxins (see Tables 63-7 and 63-8), but early and appropriate use of an antidote is a key element in managing the poisoned patient.

### Decontamination

The majority of poisonings in children are from ingestion, although exposures can also occur via inhalational, dermal, and ocular routes. The goal of decontamination is to minimize absorption of the toxic substance. The specific method employed depends on the properties of the toxin itself and the route of exposure. Regardless of the decontamination method used, the efficacy of the intervention decreases with increasing time since exposure. Decontamination should not be routinely employed for every poisoned patient. Instead, careful decisions regarding the utility of decontamination should be made for each patient and should include consideration of the toxicity and pharmacologic properties of the exposure, the route of the exposure, the time since the exposure, and the risks vs the benefits of the decontamination method.

Dermal and ocular decontamination begin with removal of any contaminated clothing and particulate matter, followed by flushing of the affected area with tepid water or normal saline. Treatment clinicians should wear proper protective gear when performing irrigation. Flushing for a minimum of 10-20 minutes is recommended for most exposures, although some chemicals (e.g., alkaline corrosives) require much longer periods of flushing. Dermal decontamination, especially after exposure to adherent or lipophilic (e.g., organophosphates) agents, should include thorough cleansing with soap and water. Water should not be used for decontamination after exposure to highly reactive agents, such as elemental sodium, phosphorus, calcium oxide, and titanium tetrachloride. After an inhalational
Gastrointestinal (GI) decontamination is a controversial topic among medical toxicologists. GI decontamination strategies are most likely to be effective in the 1st hour after an acute ingestion. GI absorption may be delayed after ingestion of agents that slow GI motility (anticholinergic medications, opioids), massive pill ingestions, sustained-release preparations, and ingestions of agents that can form pharmacologic bezoars (e.g., enteric-coated salicylates). GI decontamination at more than 1 hr after ingestion may be considered in patients who ingest toxic substances with these properties. Even rapid institution of GI decontamination with activated charcoal will, at best, bind only approximately 30% of the ingested substance. GI decontamination should never supplant excellent supportive care and should not be employed in an unstable or persistently vomiting patient. Described methods of GI decontamination include induced emesis with ipecac, gastric lavage, cathartics, activated charcoal, and whole-bowel irrigation (WBI). Of these, only activated charcoal and WBI are likely to be of clinical benefit.

**Syrup of Ipecac**

Syrup of ipecac contains 2 emetic alkaloids that work in both the central nervous system (CNS) and locally in the GI tract to produce vomiting. In the 1960s, the American Academy of Pediatrics lobbied for nonprescription availability of ipecac and in the 1980s recommended that ipecac be given to parents at the 6 mo well-child check, coupled with a discussion about poison prevention strategies. Since then, studies have failed to document a significant clinical impact from the use of ipecac and have documented multiple adverse events from its use. After a review of the evidence and assessment of the risks and benefits of ipecac use, the American Academy of Pediatrics, the American Academy of Clinical Toxicology, and the American Association of Poison Control Centers have all published statements in favor of abandoning the use of ipecac.

**Gastric Lavage**

Gastric lavage involves placing a tube into the stomach to aspirate contents, followed by flushing with aliquots of fluid, usually water or normal saline. Although gastric lavage was used routinely for many years, objective data do not document or support clinically relevant efficacy. This is particularly true in children, in whom only small-bore tubes can be used. Lavage is time-consuming and painful, and can induce bradycardia via a vagal response to tube placement. It can delay administration of more definitive treatment (activated charcoal), and under the best circumstances only removes a fraction of gastric contents. Thus, in most clinical scenarios, the use of gastric lavage is no longer recommended.

**Single-Dose Activated Charcoal**

Activated charcoal is thought to be a potentially useful method of GI decontamination, although clinical data to support this claim is limited. Charcoal is “activated” via heating to extreme temperatures, creating an extensive network of pores that provides a very large adsorptive surface area. Many, but not all, toxins are adsorbed onto its surface, thus preventing absorption from the GI tract. Charcoal is most likely to be effective when given within 1 hr of ingestion. Charged molecules (i.e., heavy metals, lithium, iron) and liquids do not bind well to activated charcoal (Table 63-9). Charcoal administration should also be avoided after ingestion of a caustic substance, because the presence of charcoal can impede subsequent endoscopic evaluation. A repeat dose of activated charcoal may be warranted in the cases of ingestion of an extended release product or, more commonly, with a significant salicylate poisoning as a result of its delayed and erratic absorption pattern.

The dose of activated charcoal is 1 g/kg in children or 50–100 g in adolescents and adults. Before administering charcoal, one must ensure that the patient’s airway is intact or protected and that the patient has a benign abdominal exam. In the awake, uncooperative adolescent or child who refuses to drink the activated charcoal, there is relatively little utility and potential morbidity associated with forcing activated charcoal down a nasogastric tube, and such practice should be avoided. Approximately 20% of children vomit after receiving a dose of charcoal, emphasizing the importance of an intact airway and avoiding administration of charcoal after ingestion of substances that are particularly toxic when aspirated (e.g., hydrocarbons). If charcoal is given through a gastric tube in an intubated patient, placement of the tube should be carefully confirmed before activated charcoal is given because instillation of charcoal directly into the lungs can have disastrous effects. Constipation is another common side effect of activated charcoal, and in rare cases, bowel perforation has been reported.

In young children, practitioners may attempt to improve palatability by adding flavorings (chocolate or cherry syrup) or giving the mixture over ice cream. Cathartics (sorbitol, magnesium sulfate, magnesium citrate) have been used in conjunction with activated charcoal to prevent constipation and accelerate evacuation of the charcoal–toxin complex. There are no data demonstrating their value and there are numerous reports of adverse effects from cathartics. Cathartics should be used with care in young children and should never be used in multiple doses because of the risk of dehydration and electrolyte imbalance.

**Whole-Bowel Irrigation**

WBI involves instilling large volumes (35 mL/kg/hr in children or 1–2 L/hr in adolescents) of a polyethylene glycol electrolyte solution (e.g., GoLYTELY) to “wash out” the entire GI tract. This technique may have some success after the ingestion of slowly absorbed substances (sustained-release preparations), substances not well adsorbed by charcoal (e.g., lithium, iron), transdermal patches, and drug packets. WBI can be combined with the use of activated charcoal, if appropriate (cocaïne or heroin body packers). In children, WBI is of greatest utility in decontaminating the gut of a child whose abdominal X-ray demonstrates multiple lead paint chips. Careful attention should be paid to assessment of the airway and abdominal exam before initiating WBI, which should never be given to a patient without bowel sounds or with signs of obstruction or ileus, or without a protected airway. Given the rate of administration and volume needed to flush the system, WBI is typically administered via a nasogastric tube. WBI is continued until the rectal effluent is clear. Complications of WBI include vomiting, abdominal pain, and abdominal distention. Bezoar formation might respond to WBI but may also require endoscopy or surgery.

**Enhanced Elimination**

Enhancing excretion is only useful for a few toxins; in these cases, enhancing elimination is a potentially lifesaving intervention that results in improved clearance of a poison that has already been absorbed.

**Urinary Alkalization**

A charged molecule, being polar and hydrophilic, does not easily cross a fat membrane. Such is the mechanism by which alkalinizing the urine enhances the elimination of some drugs that are weak acids by forming charged particles that are “trapped” within the renal tubules and thus excreted. Urinary alkalinization is accomplished via a continuous infusion of sodium bicarbonate—containing intravenous fluids, with a goal urine pH of 7.5–8. Alkalinization of the urine is most useful in managing salicylate and methotrexate toxicity.

Serum pH should be closely monitored because a serum pH of >7.55 is potentially dangerous to cellular functions. Other complications of

urinary alkalinitization include electrolyte derangements, such as hypo-
kalemia and hypocalcemia. This method of enhanced elimination is con-traindicated in patients who are unable to tolerate the large volumes of fluid needed to achieve alkalinitization, including patients with heart failure, kidney failure, pulmonary edema, or cerebral edema.

Hemodialysis
Few drugs or toxins are removed by dialysis in amounts sufficient to justify the risks and difficulty of dialysis. Toxins that are amenable to dialysis have the following properties: low volume of distribution (<1 L/kg), low molecular weight, low degree of protein binding, and high degree of water solubility. Examples of toxins for which dialysis may be useful include methanol, ethylene glycol, salicylates, theophylline, bromide, lithium, and, potentially, valproic acid. In addition to enhancing the elimination of the toxin itself, hemodialysis can also be useful to correct severe electrolyte disturbances and acid-base derange-
ments resulting from the ingestion (e.g., metformin-associated lactic acidosis).

Multiple-Dose Activated Charcoal
Whereas single-dose activated charcoal is used as a method of decon-
tamination, multiple doses of activated charcoal (MDACs) can help to enhance the elimination of some toxins. MDAC is typically given as 0.5 g/kg every 4-6 hr (for ≤24 hr) and continued until there is significant clinical improvement, including satisfactory decline of serum drug concentrations. MDACs enhance elimination via 2 proposed mechanisms: interruption of enterohepatic recirculation and “GI dialy-
sis,” which uses the intestinal mucosa as the dialysis membrane and pulls toxins from the bloodstream back into the intraluminal space, where they are adsorbed to the charcoal. The American Academy of Clinical Toxicology/European Association of Poisons Centres and Clinical Toxicologists position statement recommends MDAC in managing significant ingestions of carbamazepine, dapson, phenobarbital, quinine, and theophylline. As with single-dose activated charcoal, con-
traindications to use of MDAC include an unprotected airway and a concerning abdominal exam (e.g., ileus, distention, peritoneal signs); thus the airway and abdominal exam should be assessed before each dose. A cathartic (e.g., sorbitol) may be given with the first dose, but it should not be used with subsequent doses owing to the risk of dehydra-
tion and electrolyte derangements. Although MDAC reduces the serum level of an intoxicant quicker than without MDAC, it has not been shown to have a significant impact on outcome.

Intralipid Emulsion Therapy
A potentially life-saving intervention of infusing Intralipid emulsions is a means of sequestering fat-soluble drugs and decreasing their impact at target organs. Initial experience regarding this intervention has been developed by anesthesiologists as a reversal agent for asystole resulting from inadvertent intravenous injection of bupivacaine. There are dozens of case reports published demonstrating the dramatic and rapid recovery of premorbid poisoned patients given a dose of Intralipid. Using the same 20% Intralipid used for total parenteral nutrition, a bolus dose of 1.5 mL/kg is given over 3 min, followed by an infusion of 0.25 mL/kg/min until recovery or a total of 10 mL/kg has been infused. Lipophilic drugs (LogP >2) are potentially bound by Intralipid emulsions, including calcium channel blockers (verapamil and diltia-
zem) and tricyclic antidepressants.

SELECTED COMPOUNDS COMMONLY INVOLVED IN PEDIATRIC POISONINGS
Herbal medicines (see Chapter 64), drugs of abuse (see Chapter 114), and environmental health hazards (see Chapters 718-725) are covered elsewhere.

Pharmaceuticals
Analgesics
Acetaminophen. Acetaminophen (APAP) is the most widely used analgesic and antipyretic in pediatrics, available in multiple for-
mulations, strengths, and combinations. Consequently, APAP is com-
monly available in the home, where it can be unintentionally ingested by young children, taken in an intentional overdose by adolescents and adults, or inappropriately dosed in all ages. APAP toxicity remains the most common cause of acute liver failure in the United States, and is the number 1 cause of intentional poisoning death in the United States.

Pathophysiology. APAP toxicity results from the formation of a highly reactive intermediate metabolite, N-acetyl-p-benzoquinone imine. In therapeutic use, only a small percentage of a dose (approximately 5%) is metabolized by the hepatic cytochrome P450 enzyme CYP2E1 to N-acetyl-p-benzoquinone imine, which is then immedi-
ately conjugated with glutathione to form a nontoxic mercapturic acid conjugate. In overdose, glutathione stores are overwhelmed, and free N-acetyl-p-benzoquinone imine is able to combine with hepatic mac-
romolecules to produce hepatocellular necrosis. The single acute toxic dose of APAP is generally considered to be >200 mg/kg in children and >7.5-10 g in adolescents and adults. Repeated administration of APAP at supratherapeutic doses (>90 mg/kg/day for consecutive days) can lead to hepatic injury or failure in some children, especially in the setting of fever, dehydration, poor nutrition, and other conditions that serve to reduce glutathione stores.

Any child with a history of acute ingestion of >200 mg/kg (unusual in children younger than 6 yr old) or with an acute intentional inges-
tion of any amount should be referred to a healthcare facility for clini-
cal assessment and measurement of a serum APAP level.

Clinical and Laboratory Manifestations. Classically, 4 general stages of APAP toxicity have been described (Table 63-10). The initial signs are nonspecific (i.e., nausea and vomiting) and may not be present. Thus, the diagnosis of APAP toxicity cannot be based on clinical symptoms alone, but instead requires consideration of the combina-
tion of the patient’s history, symptoms, and laboratory findings.

If a toxic ingestion is suspected, a serum APAP level should be measured 4 hr after the reported time of ingestion. For patients who present to medical care more than 4 hr after ingestion, a stat APAP level should be obtained. APAP levels obtained <4 hr after ingestion, unless “nondetectable,” are difficult to interpret and cannot be used to estimate the potential for toxicity. Other important baseline labs include hepatic transaminases, renal function tests, and coagulation parameters.

Treatment. When considering the treatment of a patient poi-
soned or potentially poisoned with APAP, and after assessment of the ABCs, it is helpful to place the patient into one of the following 4 categories.

1. Prophylactic: By definition, these patients have a normal aspartate aminotransferase (AST). If the APAP level is known and the ingestion is within 24 hr of the level being drawn, then treatment

decisions are based on where the level falls on the Rumack-Matthew nomogram (Fig. 63-1). Any patient with a serum APAP level in the possible or probable hepatotoxicity range per the nomogram should be treated with N-acetylcysteine (NAC). This nomogram is only intended for use in patients who present within 24 hr of a single acute APAP ingestion with a known time of ingestion. If treatment is recommended, they should receive either oral Mucomyst or IV Acetadote for 24 or 21 hr, respectively. Repeat AST and APAP concentration drawn toward the end of that interval should be obtained. If the AST is normal and the APAP becomes nondetectable, then treatment may be discontinued. If the AST becomes elevated, then the patient moves into the next category of treatment (injury). If APAP is still present, treatment should be continued until the level is nondetectable. In the case of a patient with a documented APAP level, normal AST, and an unknown time of ingestion, treatment should ensue until the level is nondetectable, with normal transaminases.

The importance of instituting therapy with either IV or oral NAC no later than 8 hr from the time of ingestion cannot be overstressed. No patient, no matter the size of the ingestion, who receives NAC within 8 hr of overdose should die from liver failure. The further out from the 8 hr mark the initiation of therapy is delayed, the greater the risk of acute liver failure. Any patient presenting close to that 8 hr mark or beyond it after an APAP overdose should be empirically started on NAC pending lab results.

2. Hepatic Injury: These patients are exhibiting evidence of hepatocellular necrosis, manifested first as elevated liver transaminases (AST rises first, then the alanine aminotransferase), followed by a rise in the INR. Any patient in this category requires therapy with NAC (IV or oral). When to discontinue therapy in the clinically well patient remains controversial, but in general, the transaminases and INR have peaked and fallen significantly “toward” normal (they do not need to be normal). Most patients’ liver enzymes will peak 3 or 4 days after their ingestion.

3. Acute Liver Failure: The King’s College criteria are used to determine which patients should be referred for consideration of liver transplant. These criteria include acidemia (serum pH < 7.3) after adequate fluid resuscitation, coagulopathy (INR > 6), renal dysfunction (creatinine > 3.4 mg/dL), and grade III or IV hepatic encephalopathy (see Chapter 364). A serum lactate > 3 mmol/L (after IV fluids) adds to both the sensitivity and specificity of the criteria to predict death without liver transplant. The degree of transaminase elevation does not factor in to this decision making process.

4. Repeated Supratherapeutic Ingestion: APAP is particularly prone to unintentional overdose through the ingestion of multiple medications containing the drug or simply because people assume it to be safe at any dose. Ingestion of amounts significantly greater than the recommended daily dose for several days or more puts one at risk for liver injury. Because the Rumack-Matthew nomogram is not helpful in this scenario, a conservative approach is in order. In the asymptomatic patient, if the AST is normal and the APAP is < 10 µg/mL, then no therapy is indicated. A normal AST and an elevated APAP warrants NAC dosing for at least long enough for the drug to metabolize while the AST remains normal. An elevated AST puts the patient in the “hepatic injury” category described above. A patient presenting with symptoms (i.e., right upper quadrant pain, vomiting, jaundice) should be empirically started on NAC pending lab results.

NAC is available in oral and intravenous forms, and both are equally efficacious (see Table 63-7 for the dosing regimens of the oral vs IV form). The intravenous form is used in patients with intractable vomiting, those with evidence of hepatic failure, and pregnant patients. Oral NAC has an unpleasant taste and smell, and can be mixed in soft drink or fruit juice or given via nasogastric tube to improve tolerability of the oral regimen. Administration of IV NAC (as a standard 3% solution to avoid administering excess free water, typically in 5% dextrose), especially the initial loading dose, is associated in some patients with the development of anaphylactoid reactions (non–immunoglobulin E mediated). These reactions are typically managed by stopping the infusion; treating with diphenhydramine, albuterol, and/or epinephrine as indicated; and restarting the infusion at a slower rate once symptoms have resolved. IV NAC is also associated with mild elevation in measured INR (range: 1.2-1.5). IV dosing does, however, deliver less drug to the liver compared with the oral regimen. As a result, many toxicologists now recommend higher doses of the IV formulation in patients with large overdoses.

Transaminases, synthetic function, and renal function should be followed daily while the patient is being treated with NAC. Patients with worsening hepatic function or clinical status might benefit from more frequent lab monitoring. A patient-tailored approach is the norm for when to stop NAC therapy, for deciding whom to refer for transplantation evaluation, and often for the dose of IV NAC in patients with either very high APAP levels or signs of significant injury. Consultation with the regional poison center and medical toxicologist can help streamline the care of these patients, ultimately shortening their length of stay with potentially improved outcomes.

Salicylates. The incidence of salicylate poisoning in young children has declined dramatically since APAP and ibuprofen replaced aspirin as the most commonly used analgesics and antipyretics in
Pathophysiology. Salicylates lead to toxicity by interacting with a wide array of physiologic processes, including direct stimulation of the respiratory center, uncoupling of oxidative phosphorylation, inhibition of the tricarboxylic acid cycle, and stimulation of glycolysis and gluconeogenesis. The acute toxic dose of salicylates is generally considered to be >150 mg/kg. More significant toxicity is seen after ingestions of >300 mg/kg, and severe, potentially fatal, toxicity is described after ingestions of >500 mg/kg.

Clinical and Laboratory Manifestations. Salicylate ingestions are classified as acute or chronic, and acute toxicity is far more common in pediatric patients. Early signs of acute salicylism include nausea, vomiting, diaphoresis, and tinnitus. Moderate salicylate toxicity can manifest as tachypnea and hyperpnea, tachycardia, and altered mental status. The tachycardia results in large part from marked insensible losses from vomiting, tachypnea, diaphoresis, and uncoupling of oxidative phosphorylation. Thus, careful attention should be paid to volume status and early volume resuscitation in the significantly poisoned patient. Signs of severe salicylate toxicity include hyperthermia, coma, and seizures. Chronic salicylism can have a more insidious presentation, and patients can show marked toxicity at significantly lower salicylate levels than in acute toxicity.

Classically, lab values from a patient poisoned with salicylates reveal a primary respiratory alkalosis and a primary, elevated anion gap, metabolic acidosis. Early in the course of acute salicylism, respiratory alkalosis dominates. As the respiratory stimulation diminishes, the patient will move toward the metabolic acidosis. Hyperglycemia (early) and hypoglycemia (late) have been described. Abnormal coagulation studies and acute kidney injury may be seen but are not common.

Serial serum salicylate levels should be closely monitored (every 2-3 hr initially) until they are consistently down trending. Salicylate absorption in overdose is often unpredictable and erratic, especially with an enteric coated product, and levels can rapidly increase into the highly toxic range, even many hours after the ingestion. The Done nomogram is of poor value and should not be used. Serum and urine pH and electrolytes should be followed closely. An APAP level should be checked in any patient who intentionally overdoses on salicylates, because APAP is a common coingestant and because people often confuse or combine their nonprescription analgesics and electrolyte supplements. Salicylate toxicity can cause a noncardiogenic pulmonary edema, especially in chronic overdose; consequently, a chest x-ray is recommended in any patient in respiratory distress.

Treatment. For the patient who presents soon after an acute ingestion, initial treatment should include gastric decontamination with activated charcoal. Salicylate pills occasionally form concretions in the gastrointestinal tract, and abdominal pain. Although GI bleeding and ulcers have been described with chronic use, they are rare in the setting of acute ingestion. After massive ingestions, patients can develop marked CNS depression, anion gap metabolic acidosis, renal insufficiency, and (rarely) respiratory depression. Seizures have also been described, especially after overdose of mefenamic acid. Specific drug levels are not readily available nor do they inform management decisions. Renal function studies, acid–base balance, complete blood count, and coagulation parameters should be monitored after very large ingestions.

Oral Opioids. Opioids are a commonly abused class of medications (see Chapter 114), both in their IV and oral forms. Two specific...
oral opioids, buprenorphine and methadone, merit particular mention because of potential life-threatening toxicity in toddlers with ingestion of even 1 pill. Both agents are used in managing opioid dependence, although buprenorphine is the drug of choice. Methadone is also widely used in the treatment of chronic pain, meaning multiday prescriptions can be filled. Both drugs are readily available for illicit purchase and potential abuse. Both drugs are of great potential toxicity to a toddler, especially buprenorphine, owing to its long half-life and high potency.

Pathophysiology. Methadone is a lipophilic synthetic opioid with potent agonist effects at μ-opioid receptors, leading to both its desired analgesic effects and undesired side effects, including sedation, respiratory depression, and impaired GI motility. Methadone is thought to cause QTc interval prolongation via interactions with the human ether-a-go-go–related gene (hERG)-encoded potassium rectifier channel. Methadone has an average half-life of >25 hr, which may be extended to >50 hr in overdose.

Suboxone is a combination of buprenorphine, a potent opioid with partial agonism at μ-opioid receptors and weak antagonism at κ-opioid receptors, and naloxone. Naloxone has poor oral bioavailability but is included in the formulation to discourage diversion for intravenous use, during which it can precipitate withdrawal. Suboxone is formulated for buccal or sublingual administration; consequently, toddlers can absorb significant amounts of drug even by sucking on a tablet. Buprenorphine has an average half-life of 37 hr.

Clinical and Laboratory Manifestations. In children, methadone and buprenorphine ingestions can manifest with the classic opioid toxidrome of respiratory depression, sedation, and miosis. Signs of more-severe toxicity can include bradycardia, hypotension, and hypothermia. Even in therapeutic use, methadone is associated with a prolonged QTc interval and risk of torsades de pointes. Accordingly, an ECG should be part of the initial evaluation after ingestion of methadone or any unknown opioid. Neither drug is detected on routine urine opiate screens, although some centers have added a separate urine methadone screen. Levels of both drugs can be measured, although this is rarely done clinically and is seldom helpful in the acute setting. An exception may be in the cases involving concerns about neglect or abuse, at which point urine for gas chromatography/mass spectroscopy, the legal gold standard, should be sent to confirm and document the presence of the drug.

Treatment. Patients with significant respiratory depression or CNS depression should be treated with the opioid antidote, naloxone (see Table 63-7). In pediatric patients who are not chronically on opioids, the full reversal dose of 0.1 mg/kg (max: 2 mg/dose) should be used. In contrast, opioid-dependent patients should be treated with smaller initial doses (0.01 mg/kg), which can then be repeated as needed to achieve the desired clinical response, hopefully avoiding abrupt induction of withdrawal. Because the half-lives of methadone and buprenorphine are far longer than that of naloxone, patients can require multiple doses of naloxone. These patients may benefit from a continuous infusion of naloxone, typically started at two-thirds of the reversal dose/hr and titrated to maintain an adequate respiratory rate and level of consciousness. Patients who have ingested methadone should be placed on a cardiac monitor and have serial ECGs to monitor for the development of a prolonged QTc interval. If a patient does develop a prolonged QTc, management includes close cardiac monitoring, repletion of electrolytes (potassium, calcium, and magnesium), and having magnesium and a defibrillator readily available should the patient develop torsades de pointes.

Given the potential for clinically significant and prolonged toxicity, any toddler who has ingested methadone, even if asymptomatic, should be admitted to the hospital for at least 24 hr of monitoring. Some experts advocate a similar approach to management of buprenorphine ingestions, even in the asymptomatic patient. As we gain more experience with pediatric buprenorphine exposures, some patients who remain absolutely asymptomatic for 6-8 hr after ingestion and have a stable social setting may be candidates for earlier discharge. In the meantime, these cases should be discussed with a poison control center or medical toxicologist before determining disposition.

Cardiovascular Medications

β-Adrenergic Receptor Blockers. β Blockers competitively inhibit the action of catecholamines at the β receptor. Therapeutically, β blockers are used for a variety of conditions, including hypertension, coronary artery disease, tachyarrhythmias, anxiety disorders, migraines, essential tremor, and hyperthyroidism. Because of its lipophilicity and blockade of fast sodium channels, propranolol is considered to be the most toxic member of the β-blocker class. Overdoses of water-soluble β blockers (e.g., atenolol) are associated with milder symptoms.

Pathophysiology. In overdose, β blockers decrease chronotropy and inotropy in addition to slowing conduction through atrioventricular nodal tissue. Clinically, these effects are manifested as bradycardia, hypotension, and heart block. Patients with reactive airways disease can experience bronchospasm as a result of blockade of β2-mediated bronchodilation. β Blocks interfere with glycogenolysis and gluconeogenesis, which can sometimes lead to hypoglycemia, especially in patients with poor glycogen stores (e.g., toddlers).

Clinical and Laboratory Manifestations. Toxicity typically develops within 6 hr of ingestion, although it may be delayed after ingestion of sotalol or sustained-release preparations. The most common features of severe poisoning are bradycardia and hypotension. Lipophilic agents, including propranolol, can enter the CNS and cause altered mental status, coma, and seizures. Overdose of β blockers with membrane-stabilizing properties (e.g., propranolol) can cause QRS interval widening and ventricular dysrhythmias.

Evaluation after β-blocker overdose should include an ECG, frequent reassessments of hemodynamic status, and blood glucose. Serum levels of β blockers are not readily available for routine clinical use and are not useful in management of the poisoned patient.

Treatment. In addition to supportive care and GI decontamination as indicated, glucagon is the antidote of choice for β-blocker toxicity (see Table 63-7). Glucagon stimulates adenyl cyclase and increases levels of cyclic adenosine monophosphate independent of the β receptor. Glucagon is typically given as a bolus and, if this is effective, followed by a continuous infusion. In practice, however, glucagon is often only marginally effective, limited by its prooxygenetic effects, especially at the doses typically required. Other potentially useful interventions include calcium, vasopressors, and high-dose insulin. Seizures are managed with benzodiazepines, and QRS widening should be treated with sodium bicarbonate. Children who ingest 1 or 2 water-soluble β blockers are unlikely to develop toxicity and can typically be discharged to home if they remain asymptomatic over a 6-hr observation period. Children who ingest sustained-release products, highly lipid-soluble agents, and sotalol can require longer periods of observation before safe discharge. Any symptomatic child should be admitted for ongoing monitoring and directed therapy.

Calcium Channel Blockers. Calcium channel blockers (CCBs) are used for a variety of therapeutic indications and have the potential to cause severe toxicity, even after exploratory ingestions. Specific agents include verapamil, diltiazem, and the dihydropyridines (e.g., amlodipine, nifedipine). Of these, diltiazem and verapamil are the most dangerous in overdose.

Pathophysiology. CCBs antagonize L-type calcium channels, inhibiting calcium influx into myocardial and vascular smooth muscle cells. Verapamil works primarily by slowing inotropy and chronotropy, and it has no effect on systemic vascular resistance (SVR). Diltiazem has effects both on the heart and the peripheral vasculature. The dihydropyridines exclusively diminish SVR. Verapamil and diltiazem can significantly diminish myocardial contractility and conduction, with diltiazem also lowering SVR. By contrast, dihydropyridines will drop the SVR, leading to vasodilatation and reflex tachycardia (though this receptor selectivity may be lost after a large overdose). Because the same L-type calcium channels blocked by CCBs are also on the pancreatic islet cells, it is the norm for any patient significantly poisoned with a CCB to be hyperglycemic.

Clinical and Laboratory Manifestations. The onset of symptoms typically is soon after ingestion, although it may be delayed with ingestions of sustained-release products. Overdoses of CCBs lead
to hypotension, accompanied by bradycardia, normal heart rate, or even tachycardia, depending on the agent. One unique characteristic of CCB overdose is that patients can exhibit profound hypotension with preserved consciousness.

Initial evaluation should include an ECG, continuous and careful hemodynamic monitoring, and rapid measurement of serum glucose levels. Both the absolute degree of hyperglycemia and the percentage increase in serum glucose have been correlated with the severity of CCB toxicity in adults. The development of hyperglycemia can even preclude the development of hemodynamic instability. Blood levels of CCBs are not readily available and are not useful in guiding therapy.

Treatment. Once initial supportive care has been instituted, GI decontamination should begin with activated charcoal as appropriate. WBI may be beneficial in a stable patient after ingestion of a sustained-release product. Calcium channel blockade in the smooth muscles of the GI tract can lead to greatly diminished motility; thus, any form of GI decontamination should be undertaken with careful attention to serial abdominal exams.

Calcium salts, administered either through a peripheral IV as calcium gluconate, or via a central line as calcium chloride, help to overcome blocked calcium channels. High-dose insulin euglycemia therapy is considered the antidote of choice for CCB toxicity. An initial bolus of 1 unit/kg of regular insulin is followed by an infusion at 0.5-1 unit/kg/hr (see Table 63-6). The main mechanism of high-dose insulin euglycemia is to improve the metabolic efficiency of a poisoned heart that is in need of carbohydrates for energy (instead of the usual free fatty acids), but has minimal circulating insulin. Blood glucose levels should be closely monitored, and supplemental glucose may be given to maintain euglycemia, although this is rarely necessary in the severely poisoned patient. Additional therapies include judicious IV fluid boluses and vasopressors (often in very high doses). Cardiac pacing is rarely of value, owing to the small quantities ingested and the rapid discontinuation of the drug, or even missing 1 or 2 doses, could lead to potentially dangerous elevations in blood pressure.

Digoxin. Digoxin is a cardiac glycoside extracted from the leaves of Digitalis lanata. Other natural sources of cardiac glycosides include Digitalis purpurea (foxglove), Nerium oleander (oleander), Convallaria majalis (lily of the valley), Siberian ginseng, and the Bufo marinus toad. Therapeutically, digoxin is used in the management of heart failure and some supraventricular tachydysrhythmias. Acute overdose can occur in the setting of dosing errors (especially in younger children), unintentional or intentional medication ingestion, or exposure to plant material containing digitalis glycosides. Regarding exposure to such plants, toxicity is unusual unless the poison is concentrated in the form of a tea. Chronic toxicity can result from alteration of the digoxin dose, alteration in digoxin clearance as a result of renal impairment, or drug interactions.

Pathophysiology. Digoxin blocks the Na+, K+-ATPase (adenosine triphosphatase) pump, leading to intracellular loss of K+ and gain of Na+ and Ca++. This resulting rise in Ca++ available to the contractile myocardium improves inotropy. An increase in myocardial automaticity leads to subsequent atrial, nodal, and ventricular ectopy. Digoxin also affects nodal conduction, leading to a prolonged refractory period, decreased sinus node firing, and slowed conduction through the atrioventricular node. Impaired Na-K exchange results in dangerously high levels of serum potassium. Overall, digoxin overdose manifests as a combination of slowed or blocked conduction and increased ectopy.

Clinical and Laboratory Manifestations. Nausea and vomiting are common initial symptoms of acute digoxin toxicity, manifesting within 6 hr of overdose. Cardiovascular manifestations include bradycardia, heart block, and a wide variety of dysrhythmias. CNS manifestations consist of lethargy, confusion, and weakness. Chronic toxicity is more insidious and manifests with GI symptoms, altered mental status, and visual disturbances.

Initial assessment should include an ECG, serum digoxin level, serum potassium, and kidney function tests. The serum digoxin level should be assessed at least 6 hr after ingestion and carefully interpreted in the setting of clinical symptoms because the digoxin level alone does not entirely reflect the severity of intoxication. In acute ingestions, serum potassium is less useful as a prognostic marker and may be altered due to concomitant use of diuretics.

Digoxin has a very narrow therapeutic index. Therapeutic plasma digoxin concentrations are 0.5-2.0 ng/mL; a level >2 ng/mL is considered toxic and a level >6 ng/mL is considered potentially fatal (in chronic poisonings). Numerous drug interactions affect plasma digoxin concentrations. Medications known to increase serum digoxin concentrations include the macrolides, erythromycin and clarithromycin, spironolactone, verapamil, amiodarone, and itraconazole.

Treatment. Initial treatment includes good general supportive care and gastric decontamination with activated charcoal if the ingestion was recent. An antidote for digoxin, digoxin-specific Fab antibody fragments (Digibind or DigiFab) is available (see Table 63-7). Fab fragments bind free digoxin in both the intravascular and the interstitial spaces to form a pharmacologically inactive complex that is subsequently renally eliminated. Indications for Fab fragments include life-threatening dysrhythmias, K+ value >5-5.5 mEq/L, serum digoxin level >15 ng/mL at any time or >10 ng/mL 6 hr after ingestion, ingestion >4 mg in children or >10 mg in adults, clinically significant hypotension or other cardiovascular instability, altered mental status, and renal failure. Atropine is potentially useful in managing symptomatic bradycardia. Although digoxin has severe hyperkalemia and QRS widening on the ECG, it should not receive calcium salts, this has not been supported in the literature. Once
stabilized, consultation with a cardiologist is recommended in the management of patients chronically on digoxin, because administration of Fab fragments can lead to recurrence of the patient’s underlying dysrhythmias or dysfunction.

Iron. Historically, iron was a common cause of childhood poisoning deaths. However, preventive measures such as childproof packaging have significantly decreased the rates of serious iron toxicity in young children. Iron-containing products remain widely available, with the most potentially toxic being adult iron preparations and prenatal vitamins. The severity of an exposure is related to the amount of elemental iron ingested. Ferrous sulfate contains 20% elemental iron, ferrous gluconate 12%, and ferrous fumarate 33%. Multivitamin preparations and children’s vitamins rarely contain enough elemental iron to cause significant toxicity.

Pathophysiology. Iron is directly corrosive to the GI mucosa, leading to hematemesis, melena, ulceration, infarction, and potential perforation. Early iron-induced hypotension is caused by massive volume losses, increased permeability of capillary membranes, and venodilation mediated by free iron. Iron accumulates in tissues, including the Kupffer cells of the liver and myocardial cells, leading to hepatotoxicity, coagulopathy, and cardiac dysfunction. Metabolic acidosis develops in the setting of hypotension, hypovolemia, and iron’s direct interference with oxidative phosphorylation and the Krebs cycle. Pediatric patients who ingest >40 mg/kg of elemental iron should be referred to medical care for evaluation, although moderate to severe toxicity is typically seen with ingestions of >60 mg/kg.

Clinical and Laboratory Manifestations. Iron toxicity is classically described in 4, often overlapping, stages. The initial stage, 30 min to 6 hr after ingestion, consists of profuse vomiting and diarrhea (often bloody), abdominal pain, and significant volume losses leading to potential hypovolemic shock. Patients who do not develop GI symptoms within 6 hr of ingestion are unlikely to develop serious toxicity. The 2nd stage, 6–24 hr after ingestion, is often referred to as the “quiescent phase,” as GI symptoms typically have resolved. However, careful clinical exam can reveal subtle signs of hypoperfusion, including tachycardia, pallor, and fatigue. During the 3rd stage, occurring 12–36 hr after ingestion, patients develop multisystem organ failure, shock, hepatic and cardiac dysfunction, acute lung injury or acute respiratory distress syndrome (ARDS), and profound metabolic acidosis. Death occurs most commonly during this stage. In patients who survive, the 4th stage (4–6 wk after ingestion) is marked by formation of strictures and signs of GI obstruction.

Symptomatic patients and patients with a large exposure by history should have serum iron levels drawn 4-6 hr after ingestion. Serum iron concentrations of <500 µg/dL 4-8 hr after ingestion suggest a low risk of significant toxicity, whereas concentrations of >500 µg/dL indicate that significant toxicity is likely. Additional lab evaluation in the ill patient should include arterial blood gas, complete blood count, serum glucose level, liver function tests, and coagulation parameters. Careful attention should be paid to ongoing monitoring of the patient’s hemodynamic status. An abdominal x-ray might reveal the presence of iron tablets, though not all formulations of iron are radiopaque.

Treatment. Close clinical monitoring, combined with aggressive supportive and symptomatic care, is essential to the management of iron poisoning. Activated charcoal does not adsorb iron, and WBC remains the decontamination strategy of choice. Deferoxamine, a specific chelator of iron, is the antidote for moderate to severe iron intoxication (see Table 63-7). Indications for deferoxamine treatment include a serum iron concentration of >500 µg/dL or moderate to severe symptoms of toxicity, regardless of serum iron concentration. Deferoxamine is preferably given via continuous IV infusion at a rate of 15 mg/kg/hr. Hypotension is a common side effect of deferoxamine infusion and is managed by slowing the rate of the infusion and administering fluids and/or vasopressors as needed. Prolonged deferoxamine infusion (>24 hr) has been associated with pulmonary toxicity (ARDS) and Yersinia sepsis. The deferoxamine–iron complex can color the urine reddish (“vin rose”), although this is an unreliable indicator of iron excretion. Clear end points for deferoxamine chelation are not well defined, but therapy is typically continued until clinical symptoms resolve. Consultation with a poison control center or medical toxicologist can yield guidelines for discontinuing deferoxamine.

Oral Hypoglycemics
Oral medications used in the management of type 2 diabetes include sulfonylureas, biguanides (e.g., metformin), thiazolidinediones, and meglitinides. Of these, only the sulfonylureas and meglitinides have the potential to cause profound hypoglycemia in both diabetic and nondiabetic patients. These classes of medications are widely prescribed and thus readily available for both unintentional and intentional exposures. In toddlers, ingestion of a single sulfonylurea tablet can lead to significant toxicity.

Pathophysiology. Sulfonylureas work primarily by enhancing endogenous insulin secretion. In binding to the sulfonylurea receptor, these drugs induce closure of potassium channels, leading to membrane depolarization, opening of calcium channels, and stimulation of calcium-mediated insulin release. Even in therapeutic use, the duration of hypoglycemic action can last up to 24 hr.

Clinical and Laboratory Manifestations. Hypoglycemia and symptoms associated with hypoglycemia are the primary clinical manifestations of sulfonylurea toxicity. These signs and symptoms can include diaphoresis, tachycardia, lethargy, irritability, coma, seizures, and even focal neurologic findings. As with other hyperinsulinemic states, sulfonylurea overdoses are associated with a nonketotic hypoglycemia. In the majority of cases, hypoglycemia develops within 6 hr of ingestion but can be delayed up to 16–18 hr after ingestion. Toddlers are particularly susceptible to hypoglycemia during an overnight fast.

Treatment. Patients with symptomatic hypoglycemia should be promptly treated with dextrose. In patients with mild symptoms, oral dextrose may be sufficient. However, patients with severe symptoms or profound hypoglycemia should be treated with a bolus of IV dextrose. Continuous dextrose infusions and repeated IV dextrose boluses should be avoided if possible, because this can stimulate further insulin release and lead to recurrent and prolonged hypoglycemia. Instead, the preferred antidote for symptomatic sulfonylurea toxicity is octreotide (see Table 63-7). Octreotide is a somatostatin analog that works via inhibiting insulin release. Octreotide is given IV or SC, typically in doses of 1-2 µg/kg (50-100 µg in adults) every 6-8 hr.

Given the potential for significant hypoglycemia, toddlers with witnessed or suspected sulfonylurea ingestions should be admitted to the hospital for monitoring and serial glucose measurements, at least for 12 hr, including an overnight fast. Patients of any age who develop hypoglycemia are also candidates for admission given the prolonged duration of hypoglycemic activity. Prophylactic IV dextrose infusions are not recommended because they can mask the symptoms of toxicity and stimulate further insulin secretion. Patients who require IV dextrose and/or octreotide should be monitored until they can demonstrate euglycemia for at least 8 hr off of all therapy.

With the increasing numbers of adolescents with type 2 diabetes, pediatricians should be familiar with the toxic effects of metformin as well. Although this agent does not cause hypoglycemia, its association with lactic acidosis is well documented (Metformin Associated Lactic Acidosis–MALA). This state typically arises after a large overdose in which the agent interferes with the liver’s ability to clear lactic acid. Dangerously high serum lactate levels can result, leading to hemodynamic instability. Hemodialysis is usually the best option for patients with severe metformin-associated lactic acidosis.

Psychiatric Medications: Antidepressants
Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram) are the most commonly prescribed class of antidepressants. This trend results in large part from their wide therapeutic index and more favorable side-effect profile when compared to older agents such as tricyclic antidepressants (TCAs; amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, imipramine) and monoamine oxidase inhibitors. Other agents include the serotonin and norepinephrine reuptake inhibitors (e.g., venlafaxine) and other atypical antidepressants (e.g., bupropion).
Tricyclic Antidepressants. Although TCAs are now prescribed less commonly for depression, they remain in use for a variety of other conditions, including chronic pain syndromes, enuresis, attention-deficit/hyperactivity disorder, and obsessive compulsive disorder. TCAs can cause significant toxicity in children, even with ingestion of 1 or 2 pills (10-20 mg/kg).

Pathophysiology. TCAs achieve their desired antidepressant effects primarily via blockade of norepinephrine and serotonin reuptake. TCAs have complex interactions with other receptor types. Antagonism at muscarinic acetylcholine receptors leads to clinical features of the anticholinergic toxidrome. Antagonism at peripheral α-receptors leads to hypotension and syncope. Key to the toxicity of TCAs is their ability to block fast sodium channels, leading to impaired cardiac conduction and arrhythmias.

Clinical and Laboratory Manifestations. Cardiovascular and CNS symptoms dominate the clinical presentation of TCA toxicity. Symptoms typically develop within 1-2 hr of ingestion, and serious toxicity usually manifests within 6 hr of ingestion. Patients can have an extremely rapid progression from mild symptoms to life-threatening dysrhythmias. Patients often develop features of the anticholinergic toxidrome, including delirium, mydriasis, dry mucous membranes, tachycardia, hyperthermia, urinary retention, and slow GI motility. CNS toxicity can include lethargy, coma, myoclonic jerks, and seizures. Sinus tachycardia is the most common cardiovascular manifestation of toxicity; however, patients can develop widening of the QRS complex, premature ventricular contractions, and ventricular arrhythmias. Refractory hypotension is a poor prognostic indicator and is the most common cause of death in TCA overdose.

Treatment. Initial attention should be directed to supporting vital functions, including airway and ventilation support as needed. Gastric decontamination can be accomplished with activated charcoal in appropriate patients. Treating clinicians should obtain an ECG as soon as possible and follow serial ECGs to monitor for progression of toxicity.

Four primary effects seen at the bedside, along with their treatment recommendations, are listed here:

1. **Altered mental status.** TCA-poisoned patients can become deeply comatose relatively quickly, so careful and prompt attention to the airway and placement of an endotracheal tube is of paramount importance. The airway should be secured prior to any GI decontamination efforts.

2. **Widened QRS on the ECG.** TCAs (along with other agents such as diphenhydramine, cocaine, etc) will block the fast sodium channels on the myocardial cells, slowing the upstroke of the QRS complex. Because the effect on sodium channels is greatest within the 1st 6 hr, frequent ECGs (i.e., every 20-30 min) during this time frame are important. As the QRS approaches 160 msec, the chance of the patient developing monomorphic ventricular tachycardia rises to 30%. Sodium, usually in the form of sodium bicarbonate, is the antidote of choice. **Indications for sodium bicarbonate include a QRS duration ≥110 msec, ventricular dysrhythmias, and hypotension.** Multiple bolus doses of sodium bicarbonate, 1-2 mEq/kg each, may be needed to narrow the QRS to <110 msec. Some authors prefer to then place the patient on an infusion of sodium bicarbonate, but this may not be necessary if careful attention is paid to the QRS after the initial doses and repeat bolus dosing is provided as needed during those 1st 6-12 hr. Hypertonic (3%) saline and/or lipid emulsion therapy may be beneficial in refractory cases.

3. **Hypotension.** A direct acting vasopressor, such as norepinephrine or epinephrine, is the agent of choice. Boluses of intravenous crystalloid fluids should be used with caution to prevent fluid overload.

4. **Seizures.** Likely a result of the anticholinergic effects of TCAs, seizures are relatively common, typically brief, and should be treated with agents the work on the γ-aminobutyric acid receptor complex in the brain. Benzodiazepines are the agent of choice. Asymptomatic children should receive appropriate decontamination and be observed with continuous cardiac monitoring and serial ECGs for at least 6 hr. If any manifestations of toxicity develop, the child should be admitted to a monitored setting. Children who remain completely asymptomatic with normal serial ECGs may be candidates for discharge after 6 hr of close observation.

**Selective Serotonin Reuptake Inhibitors.** In overdose, SSRIs are considerably less toxic than TCAs. SSRIs are unlikely to cause significant toxicity in exploratory ingestions. Some data suggest that initiating SSRI therapy is associated with an increased risk of suicidal ideation and behavior (see Chapter 21).

Pathophysiology. SSRIs selectively block the reuptake of serotonin in the CNS. In contrast to TCAs and atypical antidepressants, SSRIs do not directly interact with other receptor types.

Clinical and Laboratory Manifestations. In overdose, the principal manifestations of toxicity are sedation and tachycardia. Cardiac conduction abnormalities (primarily QTc prolongation) and seizures have been described in significant overdoses, especially after ingestions of citalopram. An ECG should be part of the initial assessment after SSRI ingestion. Serum creatine kinase levels are almost always elevated in a patient with clinically significant serotonin syndrome. Although development of the serotonin syndrome is seen more often after therapeutic use or overdose of several serotonergic agents in combination, it has also been described in ingestions of SSRIs alone (Table 63-11). Clinically, serotonin syndrome describes a spectrum of altered mental status, autonomic instability, fever, and neuromuscular hyperactivity (hyperreflexia, tremors, clonus in the lower extremities more than the upper extremities). One or all of these signs may be present to varying degrees.

Treatment. Initial management includes a careful assessment for signs and symptoms of serotonin syndrome and an ECG. Most patients simply require supportive care and observation until their mental status improves and tachycardia, if present, resolves. Management of serotonin syndrome is directed by the severity of symptoms; possible therapeutic interventions include benzodiazepines in mild cases and intubation, sedation, and paralysis in patients with severe manifestations (e.g., significant hyperthermia). Because agonism at the 5-HT_{1A} serotonin receptor is thought to be primarily responsible for the development of serotonin syndrome, use of the 5HT_{1A} receptor antagonist cyproheptadine is also beneficial. Cyproheptadine is only available in an oral form.

Atypical Antidepressants. The class known as atypical antidepressants includes agents such as venlafaxine and duloxetine (serotonin and norepinephrine reuptake inhibitors), bupropion (dopamine, norepinephrine, and some serotonin reuptake blockade), and...
trazodone (serotonin reuptake blockade and peripheral α-receptor antagonism). The variable receptor affinities of these agents lead to some distinctions in their clinical manifestations and management. Clinical and Laboratory Manifestations. In overdose, venlafaxine and other serotonin and norepinephrine reuptake inhibitors are associated with cardiac conduction defects, including QRS and QTc prolongation, and seizures. Bupropion is one of the most common causes of cardiac toxicity in the pediatric population. Antipsychotic medications are commonly classified as either typical or atypical. In general, typical agents are associated with more side effects and toxicity than the atypical agents. Pathophysiology. Typical or traditional antipsychotics (i.e., haloperidol, droperidol, thioridazine, chlorpromazine, and fluphenazine) are characterized by their antagonism at D2 dopamine receptors. In therapeutic use, these agents are associated with extrapyramidal symptoms, tardive dyskinesia, and development of the neuroleptic malignant syndrome (NMS). The atypical agents (i.e., aripiprazole, clozapine, quetiapine, risperidone, ziprasidone) were developed with less dopamine (D2-receptor) antagonism in efforts to avoid these side effects and improve their efficacy in managing the “negative” symptoms of schizophrenia. Instead, these agents have complex and varied interactions with multiple receptor types, including α-receptors, serotonin receptors, muscarinic acetylcholine receptors, and histamine receptors. Clinical and Laboratory Manifestations. Typical antipsychotic toxicity commonly includes sedation, tachycardia, and prolongation of the QTc interval. Patients can present with acute dystonia, akathisia, and NMS, although these are seen less commonly in acute overdoses than in therapeutic use. The phenothiazines (e.g., thioridazine) can cause widening of the QRS interval owing to blockade of fast sodium channels. Clinically, NMS can be difficult to distinguish from serotonin syndrome. Although the presentation of atypical antipsychotic toxicity can vary based on the receptor affinities of the specific agent, sedation, tachycardia, and QTc prolongation are common. Peripheral α-receptor blockade (e.g., with quetiapine) is associated with hypotension. In therapeutic use, clozapine is associated with agranulocytosis. Diagnostic testing should include an ECG. Patients with hyperthermia or muscle rigidity should have a serum creatine kinase level sent to monitor for possible rhabdomyolysis. Antipsychotic levels are not readily available and are not helpful in managing acute poisoning. Management. Initial management involves assessing and supporting vital functions. In some patients, CNS depression may be so profound as to require intubation for airway control. Acute dystonia is treated with diphenhydramine, benztropine, and sometimes benzodiazepines. Management of NMS includes conscientious supportive care, IV fluids, cooling, benzodiazepines, and bromocriptine or dantrolene in severe cases. QTc prolongation is managed with repletion of electrolytes (especially calcium, magnesium, and potassium), continuous cardiac monitoring, overdrive pacing, IV magnesium sulfate and/or defibrillation if the patient develops torsades de pointes. Seizures typically are well controlled with benzodiazepines. Hypotension usually responds to boluses of IV fluids, though vasopressor therapy is necessary in some cases. Household Products Caustics Caustics include acids and alkalis as well as a few common oxidizing agents (see Chapter 327). Strong acids and alkalis can produce severe injury even in small-volume ingestions. Pathophysiology. Alkalis produce a liquefaction necrosis, allowing further tissue penetration of the toxin and setting the stage for possible perforation. Acids produce a coagulative necrosis, which limits further tissue penetration, though perforation can still occur. The severity of the corrosive injury depends on the pH and...
concentration of the product as well as the length of contact time with the product. Agents with a pH of <2 or >12 are most likely to produce significant injury.

**Clinical Manifestations.** Ingestion of caustic materials can produce injury to the oral mucosa, esophagus, and stomach. Patients can have significant esophageal injury even in the absence of visible oral burns. Symptoms include pain, drooling, vomiting, abdominal pain, and difficulty swallowing or refusal to swallow. Laryngeal injury can manifest as stridor and respiratory distress, necessitating intubation. In the most severe cases, patients can present in shock after perforation of a hollow viscus. Circumferential burns of the esophagus are likely to cause strictures when they heal, which can require repeated dilation or surgical correction and long-term follow-up for neoplastic changes in adulthood (see Chapter 327.2). Caustics on the skin or in the eye can cause significant tissue damage.

**Treatment.** Initial treatment of caustic exposures includes thorough removal of the product from the skin or eye by flushing with water. Emesis and lavage are contraindicated. Activated charcoal should not be used because it does not bind these agents and can predispose the patient to vomiting and subsequent aspiration. Stridor or other signs of respiratory distress should alert the provider to the need for a thorough evaluation of the airway for potential intubation or surgical airway management. Endoscopy can be performed within 12-24 hr of ingestion for prognostic and diagnostic purposes in symptomatic patients or those in whom injury is suspected on the basis of history and known characteristics of the ingested product. Endoscopy is contraindicated in any patient with signs of perforation. The use of corticosteroids or prophylactic antibiotics is not beneficial.

**Cholinesterase-Inhibiting Insecticides**

The most commonly used insecticides are organophosphates and carbamates; both are inhibitors of cholinesterase enzymes (acetylcholinesterase, pseudocholinesterase, and erythrocyte acetylcholinesterase). Most pediatric poisonings occur as the result of unintentional exposure to insecticides in and around the home or farm. The class of chemical warfare weapons known as “nerve agents” are also organophosphate compounds with a similar mechanism of action, but much greater potency.

**Pathophysiology.** Organophosphates and carbamates produce toxicity by binding to and inhibiting acetylcholinesterase, preventing the degradation of acetylcholine and resulting in its accumulation at nerve synapses. If left untreated, organophosphates form an irreversible bond to acetylcholinesterase, permanently inactivating the enzyme. This process, called aging, occurs over a variable time period depending on the characteristics of the specific organophosphate. Afterwards, a period of weeks to months is required to regenerate inactivated enzymes. In contrast, carbamates form a temporary bond to the enzymes, typically allowing reactivation of acetylcholinesterase within 24 hr.

**Clinical and Laboratory Manifestations.** Clinical manifestations of organophosphate and carbamate toxicity relate to the accumulation of acetylcholine at peripheral nicotinic and muscarinic synapses and in the CNS. Symptoms of carbamate toxicity are usually less severe than those seen with organophosphates. A commonly used mnemonic for the symptoms of cholinergic excess at muscarinic receptors is **DUMBELLS**, which stands for diarrhea/defecation, urination, miosis, bronchorrhia/bronchospasm, bradycardia, emesis, lacrimation, and salivation. Nicotinic signs and symptoms include muscle weakness, fasciculation, tremors, hypoventilation (diaphragm weakness), hypertension, tachycardia, and dysrhythmias. Severe manifestations include coma, seizures, shock, arrhythmias, and respiratory failure.

Diagnosis of poisoning is based primarily on history and physical exam findings. Red blood cell cholinesterase and pseudocholinesterase activity levels can be measured in the laboratory. These are only helpful if the patient’s known baseline. As such, these assessments are typically limited to farm workers undergoing ongoing occupational surveillance.

**Treatment.** Basic decontamination should be performed, including washing all exposed skin with soap and water and immediately removing all exposed clothing. Activated charcoal is unlikely to be of benefit as these are liquids that are rapidly absorbed. Basic supportive care should be provided, including fluid and electrolyte replacement and intubation and ventilation if necessary. The use of succinylcholine for rapid sequence intubation should be avoided as this paralytic is metabolized by the same cholinesterase enzymes now poisoned, leading to prolonged paralysis.

Two antidotes are useful in treating cholinesterase inhibitor poisoning: atropine and pralidoxime (see Table 63-7). Atropine, which antagonizes the muscarinic acetylcholine receptor, is useful for both organophosphate and carbamate intoxication. Often, large doses of atropine must be administered by intermittent bolus or via continuous infusion to control symptoms. Atropine dosing is primarily targeted to drying the respiratory secretions. Pralidoxime breaks the bond between the organophosphate and the enzyme, reactivating acetylcholinesterase. Pralidoxime is only effective if it is used before the bond ages and becomes permanent. Pralidoxime is not necessary for carbamate poisonings because the bond between the insecticide and the enzyme degrades spontaneously.

Without treatment, symptoms of organophosphate poisoning can persist for weeks, requiring continuous supportive care. Even with treatment, some patients develop a delayed polyneuropathy and a range of chronic neuropsychiatric symptoms.

**Hydrocarbons**

Hydrocarbons include a wide array of chemical substances found in thousands of commercial products. Specific characteristics of each product determine whether exposure will produce systemic toxicity, local toxicity, both, or neither. Nevertheless, aspiration of even small amounts of certain hydrocarbons can lead to serious, potentially life-threatening toxicity.

**Pathophysiology.** The most important manifestation of hydrocarbon toxicity is aspiration pneumonitis via inactivation of the type II pneumocytes and resulting surfactant deficiency (see Chapter 397). Aspiration usually occurs during coughing and gagging at the time of ingestion or vomiting after the attempted ingestion of an ali-phatic hydrocarbon. The propensity of a hydrocarbon to cause aspiration pneumonitis is inversely proportional to its viscosity, and directly proportional to its volatility. Compounds with low viscosity and high volatility, such as mineral spirits, naphtha, kerosene, gasoline, and lamp oil, spread rapidly across surfaces and cover large areas of the lungs when aspirated. Only small quantities (<1 mL) of such chemicals need be aspirated to produce significant injury. Pneumonitis does not result from dermal absorption of hydrocarbons or from ingestion in the absence of aspiration. Gasoline and kerosene are poorly absorbed, but they often cause considerable irritation of the GI mucosa as they pass through the intestines.

Certain hydrocarbons have unique toxicities and can cause symptoms after ingestion, inhalation, or dermal exposures. Several chlorinated solvents, most notably carbon tetrachloride, can produce hepatic toxicity. Methylene chloride, found in some paint removers, is metabolized to carbon monoxide. Benzene is known to cause cancer, most commonly acute myelogenous leukemia, after long-term exposure. Nitrobenzene, aniline, and related compounds can produce methemoglobinemia. A number of volatile hydrocarbons, including toluene, propellants, refrigerants, and volatile nitrites, are commonly abused by inhalation. Some of these substances, principally the halogenated hydrocarbons (which contain a chlorine, bromine, or fluorine), can sensitize the myocardium to the effects of endogenous catecholamines. This can result in dysrhythmias and “sudden sniffing death.” Chronic abuse of these agents can lead to cerebral atrophy, neuropsychologic changes, peripheral neuropathy, and kidney disease (see Chapter 114).

**Clinical and Laboratory Manifestations.** Transient, mild CNS depression is common after hydrocarbon ingestion or inhalation. Aspiration is characterized by coughing, which usually is the first clinical finding. Chest radiographs may initially be normal, but they often show abnormalities within 6 hr of exposure in patients who have aspirated. Respiratory symptoms can remain mild or progress rapidly to ARDS and respiratory failure. Fever and leukocytosis are common accompanying signs in patients with pneumonitis and don’t necessarily
Early symptoms onset of serious effects, including profound metabolic acidosis and measured by the freezing point depression method and compared with gap does not rule out ingestion of any alcohol. Serum osmolality is usually difficult based on history. Methanol blood levels are available an anion gap metabolic acidosis as the parent compound is metabolized, noted. Initially, patients have an elevated osmolar gap and then develop acidosis is well established. These visual defects may be reversible if treated early, but untreated they can lead to permanent blindness. On acidosis is delayed up to 4-12 hr after ethylene glycol ingestion, and may be delayed further with any concomitant ingestion of ethanol. Ethylene glycol blood concentrations are technically difficult to perform and are available only at some larger reference laboratories. In the absence of readily available ethylene glycol concentrations, calculation of the osmolar gap may be helpful as a surrogate marker.

Examination of the urine with a Wood lamp is neither sensitive nor specific for ethylene glycol ingestion. The earliest sign on a urinalysis of ethylene glycol poisoning is usually hematuria. Calcium oxalate crystals can be seen on urine microscopy but might not be evident early after exposure. Electrolytes (including calcium), acid–base status, kidney function, and ECG should be closely monitored in poisoned patients.

Treatment. Because methanol and ethylene glycol are rapidly absorbed, gastric decontamination is generally not of value. The classic antidote for methanol and ethylene glycol poisoning was ethanol, a preferential substrate for alcohol dehydrogenase, thus preventing the metabolism of parent compounds to toxic metabolites. Fomepizole (see Table 63-7), a potent competitive inhibitor of alcohol dehydrogenase, has almost entirely replaced the use of ethanol owing to its ease of administration, lack of CNS and metabolic effects, and overall excellent patient tolerability profile. As with all poisons, a serum concentration must be interpreted along with the time removed from exposure. A patient with a methanol level of 20 mg/dL 24 hr after exposure had a much larger dose than a patient with the same level only 1 hr after ingestion. Indications for fomepizole include ethylene glycol or methanol level >20 mg/dL, history of potentially toxic ingestion (e.g., any intentional overdose), or history of ingestion with evidence of acidosis. There are few disadvantages to giving the initial dose of fomepizole to patients with a concerning history of ingestion or lab findings, and given the dosing schedule of fomepizole (every 12 hr), this strategy buys the clinician time to confirm or exclude the diagnosis before giving a second dose. Adjunctive therapy includes folate (methanol toxicity), pyridoxine (ethylene glycol toxicity) and sodium bicarbonate infusions for both (if acidic). If a child has had an unintentional exposure and a level of the alcohol cannot be obtained, a reasonable approach is to follow serum chemistries every 4 hr until the child is 12 hr removed from the exposure. If the bicarbonate level on the chemistry panel does not fall in that time frame, then a toxic exposure is unlikely (assuming no ethanol is present).

Hemodialysis effectively removes ethylene glycol, methanol, and their metabolites (except calcium oxalate) and corrects acid–base and electrolyte disturbances. Fomepizole should be given both before and immediately after dialysis. Indications for dialysis include a methanol level of >50 mg/dL, acidosis, severe electrolyte disturbances, and renal failure. However, in the absence of acidosis and kidney failure, even massive ethylene glycol ingestions have been managed without dialysis. Methanol is another story, because its elimination in the setting of alcohol dehydrogenase inhibition is very prolonged, thus often warranting dialysis to remove the parent compound. Therapy (fomepizole and/or dialysis) should be continued until ethylene glycol and methanol levels are <20 mg/dL. While the visual effects from

Toxic Alcohols Methyl alcohol is commonly found in windshield washer fluids, deicers, paint removers, fuel additives, liquid fuel canisters, and industrial solvents. Ethylene glycol is commonly found in antifreeze. Unintentional ingestion is the most common exposure in children, and small-volume ingestions of concentrated products can theoretically cause toxicity. The pathophysiology, acid–base derangements, and treatment of both chemicals are similar, although they differ in their primary end-organ toxicity. In both cases, the metabolites of the parent compounds are responsible for the serious clinical effects that can follow exposure.

Isopropyl alcohol (rubbing alcohol, hand sanitizers) causes intoxication similar to that associated with ethanol but can also cause a hemorrhagic gastritis and myocardial depression in massive ingestions. Unlike ethylene glycol and methanol, isopropyl alcohol is metabolized to a ketone and does not cause a metabolic acidosis. Management is similar to that of ethanol ingestions (see Chapter 114) and is not further discussed here.

Methanol Pathophysiology. Methanol is oxidized in the liver by alcohol dehydrogenase to formaldehyde, which is further oxidized to formic acid by aldehyde dehydrogenase. Toxicity is caused primarily by formic acid, which inhibits mitochondrial respiration.

Clinical and Laboratory Manifestations. Drowsiness, mild inebriation, nausea, and vomiting develop early after ingestion. The onset of serious effects, including profound metabolic acidosis and visual disturbances, is often delayed for up to 12-24 hr as the parent methanol is undergoing metabolism to its toxic metabolites. This metabolism is further slowed if ethanol has also been ingested, since the liver will preferentially metabolize ethanol. Visual disturbances include blurred or cloudy vision, constricted visual fields, decreased acuity, and the “feeling of being in a snowstorm” appear only after acidosis is well established. These visual defects may be reversible if treated early, but untreated they can lead to permanent blindness. On exam, dilated pupils, retinal edema, and optic disc hyperemia may be noted. Initially, patients have an elevated osmolar gap and then develop an anion gap metabolic acidosis as the parent compound is metabolized to formic acid.

In young children, determining if a significant exposure has occurred is usually difficult based on history. Methanol blood levels are available at some laboratories and should be sent after a concerning exposure. If methanol blood levels are not readily available, estimation of an osmolar gap may be used as a surrogate marker, but a normal osmolar gap does not rule out ingestion of any alcohol. Serum osmolality is measured by the freezing point depression method and compared with a calculated serum osmolarity.

Treatment. Treatment is as discussed for ethylene glycol toxicity.
methanol poisoning are usually permanent, the kidney injury from ethylene glycol injury is not. Patients requiring hemodialysis after ethylene glycol poisoning will almost always recover complete renal function within 2-6 wk. Consultation with a poison control center, medical toxicologist, and nephrologist may be helpful in managing toxic alcohol ingestions.

**Plants**

Exposure to plants, both inside the home and outside in backyards and fields, is one of the most common causes of unintentional poisoning in children. Fortunately, the majority of ingestions of plant parts (leaves, seeds, flowers) result in either no toxicity or mild, self-limiting effects. However, ingestion of certain plants (Table 63-12 outlines some of the most toxic plants) can lead to serious toxicity.

The potential toxicity of a particular plant is highly variable, depending on the part of the plant involved (flowers are generally less toxic than the root or seed), the time of year, growing conditions, and the route of exposure. Assessment of the potential severity after an exposure is also complicated by the difficulty in properly identifying the plant. Many plants are known by several common names, which can vary among communities. Poison control centers have access to professionals who can assist in properly identifying plants. They also are well versed in the common poisonous plants in their service area and the seasons when they are more abundant. For these reasons, consultation with the local poison control center may be very helpful in the management of these ingestions.

For potentially toxic plant ingestions, consider decontamination with activated charcoal in patients who present within 1-2 hr of ingestion; otherwise, treatment is primarily supportive and based on symptoms. The most common manifestation of toxicity after plant ingestion is GI upset, which can be managed with antiemetics and fluid and electrolyte support. Table 63-12 outlines management strategies for a few specific toxicities.

**Toxic Gases**

**Carbon Monoxide**

Although many industrial and naturally occurring gases pose a health risk by inhalation, the most common gas involved in pediatric exposures is carbon monoxide (CO). CO is a colorless, odorless gas produced during the combustion of any carbon-containing fuel. The less efficient the combustion, the greater the amount of CO produced. Wood-burning stoves, kerosene heaters, old furnaces or hot water heaters and automobiles are a few of the potential sources of CO, as is any closed space fire.

**Pathophysiology.** CO binds to hemoglobin with an affinity >200 times that of oxygen, forming carboxyhemoglobin (HbCO). In doing so, CO displaces oxygen and creates a conformational change in hemoglobin that impairs the delivery of oxygen to the tissues, leading to tissue hypoxia. HbCO levels are not well correlated with clinical signs of toxicity, likely because CO interacts with multiple proteins in addition to hemoglobin. CO binds to cytochrome oxidase, disrupting cellular respiration. CO displaces nitric oxide (NO) from proteins, allowing NO to bind with free radicals to form the toxic metabolite peroxynitrite. NO is also a potent vasodilator, in part responsible for clinical symptoms including headache, syncope, and hypotension.

**Clinical and Laboratory Manifestations.** Early symptoms are nonspecific and include headache, malaise, nausea, and vomiting. These symptoms are often misdiagnosed as indicating flu or food poisoning. At higher exposure levels, patients can develop mental status changes, confusion, ataxia, syncope, tachycardia, and tachypnea. Severe poisoning is manifested by coma, seizures, myocardial ischemia, acidosis, cardiovascular collapse, and potentially death. On exam, patients might have cherry-red skin. Emergency department evaluation should include an arterial or venous blood gas with HbCO determined by co-oximetry, and lactate assays. Severe poisoning, defined as a HbCO level >25%, abnormal cerebellar examination, and pregnancy. Consultation with a poison control center, medical toxicologist, or HBO facility can assist clinicians in determining which patients could benefit from HBO therapy. Sequelea of CO poisoning include persistent and delayed cognitive and cerebellar effects. HBO advocates believe that the risk of such sequelae is minimized through the delivery of 100% oxygen at 3 atmospheres of pressure. Patients are typically treated with oxygen, via either non-rebreather or a hyperbaric chamber, for between 6 and 24 hr. Prevention of CO poisoning should involve educational initiatives and the use of home CO detectors.

**Hydrogen Cyanide**

**Pathophysiology.** Cyanide inhibits cytochrome oxidase, part of the electron transport chain, interrupting cellular respiration and leading to profound tissue hypoxia. Patients may be exposed to hydrogen cyanide gas in the workplace (manufacturing of synthetic fibers, nitriles, and plastics) or via smoke inhalation in a fire.

**Clinical and Laboratory Manifestations.** Onset of symptoms is rapid after a significant exposure. Clinical manifestations of toxicity include headache, agitation and confusion, sudden loss of consciousness, tachycardia, cardiac dysrhythmias, and metabolic acidosis. Cyanide levels can be measured in whole blood, but they are not readily available at most institutions. A severe lactic acidosis (lactate >10 mmol/L) in fire victims suggests cyanide toxicity. Impaired oxygen extraction by tissues is implied by elevated mixed venous oxygen saturation, another laboratory finding suggesting cyanide toxicity.

**Treatment.** Treatment includes removal from the source of exposure, rapid administration of high concentrations of oxygen, and antidotal therapy. The cyanide antidote kit includes nitrates (amyl nitrite and sodium nitrite) used to produce methemoglobin, which then reacts with cyanide to form cyanomethemoglobin (see Table 63-7). The third part of the kit is sodium thiosulfate, given to hasten the metabolism of cyanomethemoglobin to hemoglobin and the less-toxic thiocyanate. In patients for whom induction of methemoglobinemia could produce more risk than benefit, the sodium thiosulfate component of the kit may be given alone. The FDA has approved hydroxocobalamin (a form of vitamin B12) for use in known or suspected cyanide poisoning. This antidote reacts with cyanide to form the nontoxic cyanocobalamin, which is then excreted in urine. Side effects of hydroxocobalamin include red discoloration of the skin and urine, transient hypertension, and interference with colorimetric lab assays. Overall, the safety profile of hydroxocobalamin appears superior to that of the cyanide antidote kit; thus this is now the preferred antidote for cyanide poisoning.

**Some Miscellaneous Toxic Agents Found in the Home**

**Single-Use Detergent Sacs**

Commonly known as laundry “pods” for clothing, these products look like candy to many children. When bitten into, a relatively large dose of concentrated detergent is expelled under pressure onto the child’s posterior pharynx and vocal cords. This can lead to stridor and other signs of respiratory distress. Occasionally, and for unknown reasons, these children may also develop altered mental status. Supportive care with attention to any airway and breathing issues is warranted. Admission to the hospital is often indicated. It should be noted, that these are not considered caustic ingestions. The pH of these products is in the neutral zone. As such, upper GI endoscopy is rarely indicated. Curiously, laundry detergent drank from a bottle is rarely of significant concern.
Chapter 63  •  Poisoning

## Batteries

Any disk or button style battery lodged in the esophagus or airway should be considered a true emergency warranting immediate referral to an endoscopist for removal. These batteries can cause necrosis of the tissues to which they are lodged via continued electrical discharge and/or leaking of their contents (the former is likely the primary method of injury). Mucosal contact for even 2 hr might induce necrosis. Once past the lower esophageal sphincter, button or even larger batteries (e.g., AA, AAA size) can usually be allowed to pass through the GI tract with close follow up.

**Bibliography is available at Expert Consult.**

**Electric Dishwasher Detergent**

Especially when in the form of crystals, these products are highly alkaline (pH >13) and exposure via ingestion can lead to significant burns to the vocal cords and GI tract. Admission for upper GI endoscopy is usually indicated.

**Magnets**

Most foreign body ingestions are allowed to pass through the GI tract once they are known to have passed into the stomach. However, ingestion of 2 or more magnets (unless they are very weak refrigerator style magnets) cause concern for bowel obstruction and/or perforation. Admission for attempted retrieval via endoscopy or clearance via WBI is to be considered.
Complementary Therapies and Integrative Medicine
Kathi J. Kemper and Paula M. Gardiner

Integrative medicine focuses on promoting physical, mental, emotional, spiritual, social, educational, and occupational well-being in the context of a medical home in a healthy family and community. The foundations of integrative medicine are health-promoting practices including optimal nutrition and dietary supplements to avoid deficiencies; avoiding intake of addictive substances such as nicotine and illicit drugs; physical activity, adequate sleep, a healthy environment, and supportive social relationships. Evidence-based complementary therapies such as herbal remedies and other dietary supplements, massage, chiropractic, and other forms of bodywork, yoga, tai chi, meditation practices, hypnosis, guided imagery, biofeedback, and acupuncture may also be used. Although prayer and healing rituals are sometimes included under the rubric of complementary and integrative therapies, they are not covered in this chapter.

Not including multivitamins and mineral supplements (such as iron and calcium), the estimated prevalence of complementary and alternative medicine use in the United States by youth younger than 18 yr of age in 2007 was 8.7 million; the most common therapies included natural products, chiropractic, and deep breathing. Use of complementary therapies is most common among youth with chronic, incurable, or recurrent conditions such as asthma, autism, cancer, depression, and pain. For example, complementary therapies were used by 42-71% of pediatric patients in a 2013 study of specialty outpatient clinics in Canada; the therapies most commonly used by these patients were dietary supplements. Side effects were uncommon and most were minor.

**Dietary Supplements**

Under the 1994 Dietary Supplement Health and Education Act, a dietary supplement is a product taken by mouth that contains a dietary ingredient intended to supplement the diet. These may include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites. Dietary supplements are the most commonly used complementary therapies for children and adolescents (Table 64-1). Some uses are common and recommended, such as vitamin D supplements for breastfed infants and probiotics to prevent *Clostridium difficile*-associated diarrhea, whereas other uses are more controversial, such as using herbal products to treat otitis media.

In the United States, dietary supplements do not undergo the same stringent evaluation and postmarketing surveillance as prescription medications. Although they may not claim to prevent or treat specific medical conditions, product labels may make structure-function claims. For example, a label may claim that a product promotes a healthy immune system, but it may not claim to cure the common cold.

According to the 2007 National Health Interview Survey, 37% of children in the United States used dietary supplements, with the majority using multivitamin and mineral products (31%) exclusively. Use of dietary supplements is most common among children whose families have higher income and education and whose parents use them; among older children; and among those suffering from chronic conditions.

Despite this widespread use, many patients and their parents who use dietary supplements do not talk with their physician about their use. Several guidelines have called for more complete dietary supplement history taking by healthcare professionals. The Joint Commission recommends that clinicians routinely ask patients about their use of dietary supplements and include this information as part of the medication reconciliation process.

**Dietary Supplement Safety**

Dietary supplements may have safety issues in children, though toxicity is much less common with nonprescription dietary supplements than with prescription medications. Toxicity depends on dose, use of other medications, and the underlying medical condition of the child. Modern use of a dietary supplement (e.g., ephedra for weight loss) may not reflect its traditional use (e.g., ephedra as a component of a traditional Chinese medicine tea in small doses to improve allergic or respiratory symptoms). Moreover, herbs that are apparently safe for most adults may be more hazardous in specific conditions (e.g., newborns, patients with impaired renal or hepatic function), under special circumstances (e.g., after organ transplantation or other surgery), or when combined with prescription medications. Some natural products are toxic in and of themselves (Table 64-2). Acute hepatic toxicity and death can result from ingestion of even small amounts of *Amanita* mushrooms. Even when a product is safe when used correctly, it can cause mild or severe toxicity when used incorrectly. Although peppermint is a commonly used and usually benign gastrointestinal spasmylytic included in after-dinner mints, it can exacerbate gastroesophageal reflux. Probiotics are generally safe when taken orally, but in an immune-compromised patient in an ICU setting, they may (rarely) cause sepsis.

</tbody>
</table>
Although there are good manufacturing practices for dietary supplements in the United States, dietary supplement labels might not accurately reflect the contents or concentrations of ingredients. Because of natural variability, variations of 10-1,000-fold have been reported for many popular herbs, even across lots produced by the same manufacturer. Herbal products may be unintentionally contaminated with pesticides, microbial agents or products, or the wrong herb that was misidentified during harvesting. Products from developing countries may be unintentionally contaminated with mercury, cadmium, arsenic, or lead, either from unintentional contamination during manufacturing or from intentional additions by producers who believe that these metals have therapeutic value. Approximately 30-40% of Asian patent medicines include potent pharmaceuticals, such as analgesics, antibiotics, hypoglycemic agents, or corticosteroids; typically, the labels for these products are not written in English and do not note the inclusion of pharmaceutical agents. Even conventional mineral supplements, such as calcium, have been contaminated with lead or had significant problems with product variability.

Many families use supplements concurrently with medications, posing hazards of interactions (Table 64-3). St. John’s wort induces CYP3A4 activity of the P450 enzyme system and thus can enhance elimination of most drugs, including digoxin, cyclosporine, protease inhibitors, oral contraceptives, and numerous antibiotics, leading to...

GI, gastrointestinal.

Subtherapeutic serum levels. In contrast, St. John’s wort may enhance the risk of the serotonin syndrome in patients on selective serotonin reuptake inhibitor agents, increase the sedation of opioids, increase the photosensitivity reactions of certain drugs, and increase the toxicity of propofol and sevoflurane.

Many folk medicine are named based on their natural language (Tables 64-4 and 64-5), which must be taken into consideration when treating specific ethnic populations.

Dietary supplement efficacy
Evidence about the effectiveness of dietary supplements to prevent or treat pediatric problems is mixed, depending on the product used and condition treated. Some herbal products may be helpful adjunctive treatments for common childhood problems; some herbs have proved helpful for colic (fennel and the combination of chamomile, fennel, vervain, licorice, and balm mint), nausea (ginger), irritable bowel syndrome (peppermint), and diarrhea (probiotics).

Massage and chiropractic
Massage is commonly provided at home by parents and by professional massage therapists, physical therapists, and nurses in clinical settings. Infant massage is routinely provided in many neonatal intensive care units to promote growth and development in preterm infants. Massage also has been demonstrated to be beneficial for pediatric patients suffering from asthma, insomnia, colic, cystic fibrosis, and juvenile ideopathic arthritis. Massage therapy is generally safe. Professional massage practice is regulated by state governments; more than 40 states license massage therapists, and 3 offer statewide independent certification.

More than 50,000 chiropractors are licensed in the United States, including licensure in all 50 states. Chiropractic care is covered by most major insurers. Up to 14% of all chiropractic visits are for pediatric patients, not including care provided by chiropractors working for athletic departments or professional teams. While chiropractic care may be useful for treating minor musculoskeletal injuries, parents need to be cautioned not to rely on chiropractic as the primary treatment for serious conditions, such as neurologic deficits, cancer or autism; data suggest that severe complications are possible.

Mind–body therapies
Mind–body therapies such as slow, deep breathing, meditation, guided imagery, biofeedback, hypnosis, tai chi, and yoga, are the second most commonly used group of complementary therapies in pediatrics. These practices can be learned informally through books, YouTube videos, CDs, DVDs, smart phone applications, or classes, or in therapeutic sessions with health professionals, such as psychologists and social workers (Table 64-6). Substantial research suggests that such practices can aid in reducing anxiety, insomnia, and stress-related conditions including migraine headaches and functional abdominal pain. They can also help patients struggling with chronic pain.

ACUPUNCTURE
Modern acupuncture incorporates treatment traditions from China, Japan, Korea, France, and other countries. In the United States, acupuncturists are licensed to practice in 43 states, and acupuncture services are offered by more than 30% of North American academic pediatric pain treatment programs. The technique that has undergone most scientific study involves penetrating the skin with thin, solid, metallic needles manipulated by hand or by electrical stimulation. Variants include rubbing (shiatsu), heat (moxibustion), lasers, magnets, pressure (acupressure), or electrical currents.

Although most pediatric patients are averse to needles, patients who suffer from severe chronic pain or nausea may be amenable to trying acupuncture and often report that it is helpful. Acupuncture can offer significant benefits in the treatment of recurrent headache, anxiety, back and other types of pain, depression, and nausea. As with any therapy involving needles, infections and bleeding can occur, but more serious complications, such as pneumothorax, occur in <1 in 30,000 treatments.

Bibliography

Acutely ill children pose a challenge to a busy pediatrician’s office. Illnesses can span the spectrum from simple viral infections to life-threatening emergencies. Pediatricians need to distinguish between patients who can be managed with close outpatient follow-up and those that need to be stabilized and transported to a higher level of care. Although patients of all ages can present with similar symptoms, the etiology of the illness can be age-dependent. The initial approach must focus on the general evaluation and stabilization of the acutely ill infant and child.

HISTORY

A thorough history is paramount to arriving at the correct diagnosis. Obtaining an accurate history from young patients is challenging, and parents often provide the most important information. On the basis of the chief complaint(s), the pediatrician must ask open-ended questions that help distinguish between common and potentially life-threatening entities. Common complaints leading to acute care visits for potential emergencies include fever, altered mental status, vomiting, respiratory distress, and abdominal pain.

Fever is the most common reason for a sick child visit. Most fevers are the result of self-limited viral infections. However, pediatricians need to be aware of the age-dependent potential for serious bacterial infections (e.g., urinary tract infections, sepsis, meningitis, pneumonia, dysentery, osteoarticular infection). During the first 2-3 mo of life, the neonate is at risk for sepsis caused by pathogens that are uncommon in older children. These organisms include group B streptococcus, Escherichia coli, Listeria monocytogenes, and herpes simplex virus. In neonates, the history must include maternal obstetric information and the patient’s birth history. Risk factors for sepsis include maternal group B streptococcus colonization, prematurity, chorioamnionitis, and prolonged rupture of membranes. If there is a maternal history of sexually transmitted infections during the pregnancy, the differential diagnosis must be expanded to include those pathogens. Septic infants can present with lethargy, poor feeding, grunting respirations, and cool or mottled extremities, in addition to fever (or hypothermia). Infants with fever, irritability, and a bulging fontanel should be evaluated for meningitis. As the infant matures beyond 3 mo of age, the bacterial pathogens that usually cause bacteremia, sepsis, and meningitis are Streptococcus pneumoniae, Haemophilus influenzae type b, and Neisseria meningitidis. Urosepsis secondary to an E. coli urinary tract infection also needs to be considered. Immunization against some serotypes of S. pneumoniae has markedly reduced the occurrence of occult bacteremia and serious infections caused by that organism, as has immunization against H. influenzae type b. These remain potential concerns in those children not fully immunized against these pathogens. Other ailments that manifest with fever include septic arthritis and osteomyelitis, juvenile idiopathic arthritis, and Kawasaki disease. Children with a septic joint generally present with only 1 joint that is painful and often have pseudoparalysis of that joint. In contrast, patients with juvenile rheumatoid arthritis may present with pain, stiffness, swelling, and warmth of several joints. The diagnosis of Kawasaki disease should be considered if the patient meets the diagnostic criteria for this illness although some patients may have an atypical or incomplete presentation (see Chapter 166).

For patients presenting with altered mental status, the pediatrician should inquire about the presence of other symptoms, such as fever or headache. Screening questions should be asked regarding feeding changes, medications in the household, or the possibility of trauma. Parents will often describe a febrile child as “lethargic.” but further questioning will reveal a tired-appearing child who interacts appropriately when the child has defervesced. Febrile patients need to be differentiated from the lethargic patient who presents with sepsis or meningitis. Infants with meningitis or sepsis may have a history of irritability, inconsolability, poor feeding, grunting respirations, seizures, decreased urine output, and/or color changes such as pallor, mottling, or cyanosis. Patients with poisonings or inborn errors of metabolism can also present with lethargy, poor feeding, unusual odors, seizures, and/or vomiting. Nonaccidental trauma should always be considered in a lethargic infant. Older children may present with altered mental status as a result of meningitis/encephalitis, trauma, or ingestions. Children with meningitis may have a history of fever and complaints of neck pain; other associated symptoms can include rash, headache, photophobia and/or vomiting. Children with ingestions can present with other abnormal neurologic symptoms such as ataxia, slurred speech, seizures, or characteristic constellations of vital sign changes and other physical findings (toxidromes).

Vomiting is a very common complaint of intestinal, other abdominal (e.g., pancreas, liver) or nongastrointestinal (e.g., hyperammonemia, increased intracranial pressure, poisoning) origin and may be a nonspecific sign of systemic illness. Questions to ask include about the presence of bilious or bloody emesis, abdominal distention, weight changes, presence of diarrhea, obstipation or hematochezia, history of trauma, and presence of headache. Although common causes of vomiting are gastroesophageal reflux and viral gastroenteritis, the pediatrician needs to be aware of other serious causes. In the infant, bilious emesis and abdominal distention and/or pain are worrisome for obstruction, as may be seen with malrotation with midgut volvulus or Hirschsprung disease. It is important to consider extraabdominal causes of vomiting in the neonate, including hydrocephalus, incarcerated hernia, inborn errors of metabolism, and nonaccidental trauma. Markedly increasing head circumference or a bulging fontanel can be the result of congenital hydrocephalus or can signal the presence of subdural hematomas from nonaccidental trauma. An infant who appears immediately hungry after projectile vomiting suggests a differential diagnosis of pyloric stenosis. In an older child, the differential diagnosis includes intussusception, incarcerated hernia, diabetic ketoacidosis, appendicitis, poisonings, and trauma. Patients with intussusception may present with vomiting and colicky abdominal pain. A history of increased urination in the presence of vomiting may herald the diagnosis of diabetes mellitus. Patients with headache and vomiting may present with an increased intracranial pressure and should be questioned about neurologic changes, meningismus, and fever.

Parents can interpret different symptoms as respiratory distress. Tachypnea secondary to fever is often a source of parental anxiety. Parents of newborn infants are sometimes alarmed by the presence of periodic breathing. Normal variations in respiratory patterns must be distinguished from true respiratory distress. Parents need to be questioned regarding associated symptoms such as fever, limitation of neck movement, drooling, choking, and the presence of stridor or wheezing.
A history of apnea or cyanosis warrants further investigation. Although wheezing is often secondary to bronchospasm, it can also be caused by cardiac disease or congenital anomalies such as vascular rings. Infants with congenital heart defects may be tachypneic but may lack any signs of respiratory distress as a compensatory mechanism for shock or metabolic acidosis. Parents often confuse and interpret stridor as wheezing, and care should be taken to differentiate the two. Stridor is most commonly caused by croup. However, anatomic abnormalities such as laryngeal webs, laryngomalacia, subglottic stenosis, and paralyzed vocal cords also cause stridor. Toddlers who present with wheezing or stridor after a coughing or choking episode should be evaluated for a foreign body aspiration. In toxic-appearing children with stridor, the pediatrician should consider epiglottitis, bacterial tracheitis, or a rapidly expanding retropharyngeal abscess. The incidence of epiglottitis has markedly declined with the advent of the H. influenzae type b (Hib) vaccine, but remains a possibility in the unimmunized or partially immunized patient. Children with retropharyngeal abscesses may also present with drooling and limitation of neck movement (especially hyperextension) after a recent upper respiratory infection or penetrating mouth injury.

Abdominal pain is another frequent complaint. Often this symptom is caused by a minor illness such as constipation, functional abdominal pain, urinary tract infection, or gastroenteritis. Parents should be questioned about associated symptoms including stooling patterns, abdominal distention, fever, urinary symptoms, and vomiting. In neonates, a tender abdomen is concerning for the presence of a small bowel obstruction; these infants tend to appear ill. There may be a history of vomiting and decreased or no stooling. Pediatricians should be wary of neonates with abdominal tenderness and bloody stools, as 10% of cases of necrotizing enterocolitis occur in term infants. Infants with milk protein intolerance can also present with bloody stools, but these infants are well-appearing and do not have abdominal tenderness. In older patients, the differential diagnosis for a potential emergency with abdominal pain expands to include intussusception and appendicitis. Patients with intussusception can present in a variety of ways, ranging from having episodes of colicky abdominal pain, but otherwise well in between episodes, to being lethargic or in shock. The diagnosis of appendicitis in the child younger than 3 yr is extremely difficult because children in this age group do not localize their pain well. Often the diagnosis is made after the appendix has ruptured.

The child’s past medical history also needs to be obtained. It is important to be aware of any underlying chronic problems that might predispose the child to recurring infections or a serious acute illness. The child with sickle cell anemia is at increased risk for bacteremia, as well as painful vasoocclusive crisis. A careful review of systems can help in identifying the nature of the acute illness, as well as any complications needing intervention, such as dehydration accompanying an otherwise minor viral illness.

**PHYSICAL EXAM**

Observation is important in the evaluation of the acutely ill child. Most observational data that the pediatrician gathers during an acute illness should focus on assessing the child’s response to stimuli. Do they awaken easily with a stimulus? Do they smile and interact with the examiner? Can the crying child be consoled by the parents’ comforting? Assessing responses to stimuli requires knowledge of normal responses for different age groups, the manner in which those normal responses are elicited, and to what degree a response might be impaired. Thus, the pediatrician must be both clinically and developmentally oriented.

During the physical examination, the pediatrician seeks evidence of illness. The portions of the physical examination that require the child to be most cooperative are completed first. Initially, it is best to seat the child on the parent’s lap; the older child may be seated on the examination table. It is also important to assess the child’s willingness to move and ease of movement. It is reassuring to see the child moving about on the parent’s lap with ease and without discomfort. Vital signs are often overlooked but are invaluable in assessing ill children. The degree of fever, the presence of tachycardia out of proportion to the fever, and the presence of tachypnea and hypotension all suggest a serious infection. The respiratory evaluation includes determining respiratory rate, the presence or absence of hypoxia by pulse oximetry, and noting any evidence of inspiratory stridor, expiratory wheezing, grunting, coughing, or increased work of breathing (e.g., retractions, nasal flaring, belly breathing). Because acute infections in children are most often caused by viral infections, the presence of nasal discharge may be noted. It is possible at this time to assess the skin for rashes. Frequently, viral infections cause an exanthem and many of these eruptions are diagnostic (e.g., the reticulated rash and “slapped-cheek” appearance of parvovirus infections or the typical appearance of hand-foot-and-mouth disease caused by coxsackieviruses). The skin examination may also yield evidence of more serious infections (bacterial cellulitis or petechiae and purpura associated with bacteremia). Cutaneous perfusion should be assessed by warmth and capillary refill time. When the child is seated and is least perturbed, an assessment of the fontanel can be completed; the examiner can determine whether the fontanel is depressed, flat, or bulging.

During this initial portion of the physical examination, when the child is most comfortable, the heart and lungs are auscultated. In the acutely febrile child, because of the relatively frequent occurrence of respiratory illnesses, it is important to assess adequacy of air entry into the lungs, equality of breath sounds, and evidence of adventitial breath sounds, especially wheezes, rales, and rhonchi. The coarse sound of air moving through a congested nasal passage is frequently transmitted to the lungs. The examiner can become attuned to these coarse sounds by placing the stethoscope near the child’s nose and then compensating for this sound as the chest is auscultated. The cardiac examination is next; findings such as pericardial friction rub, loud murmurs, and distant heart sounds may indicate an infectious process involving the heart. The eyes are examined to identify features that might indicate an infectious process. Often, viral infections result in a watery discharge or redness of the bulbar conjunctivae. Bacterial infection, if superficial, results in purulent drainage; if the infection is more deep-seated, tenderness, swelling, and redness of the tissues surrounding the eye are present, as well as proptosis, reduced visual acuity, and altered extraocular movement. The extremities may then be evaluated not only for ease of movement but also for the possibility of swelling, heat, or tenderness; such abnormalities may indicate focal infections.

The components of the physical examination that are more bothersome to the child are completed last. This is best done with the patient on the examination table. Initially, the neck is examined to assess for areas of swelling, redness, or tenderness, as may be seen in cervical adenitis. Resistance to neck movement should prompt evaluation for signs of meningeal irritation (i.e., Kernig and Brudzinski signs) or a retropharyngeal abscess. During examination of the abdomen, the diaphragm is removed. The abdomen is inspected for distention. Auscultation is performed to assess adequacy of bowel sounds, followed by palpation. The child often fusses as the abdomen is auscultated and palpated. Every attempt should be made to quiet the child; if this is not possible, increased fussing as the abdomen is palpated may indicate tenderness, especially if this finding is reproducible. In addition to focal tenderness, palpation may elicit involuntary guarding or rebound tenderness (including tenderness to percussion); these findings indicate peritoneal irritation, as is seen in appendicitis. The inguinal area and genitals are then sequentially examined. The child is then placed in the prone position, and abnormalities of the back are sought. The spine and costovertebral angle areas are percussed to elicit any tenderness; such a finding may be indicative of vertebral osteomyelitis or diskitis and pyelonephritis, respectively.

Examining the ears and throat completes the physical examination. These are usually the most bothersome parts of the examination for the child, and parents frequently can be helpful in minimizing head movement. During the oropharyngeal examination, it is important to document the presence of enanthemas; these may be seen in many infectious processes, such as hand-foot-and-mouth disease caused by coxsackievirus. This portion of the examination is also important in documenting inflammation or exudates on the tonsils, which may be viral or bacterial.
Repeating portions of the assessment may be indicated. If the child cried continuously during the initial clinical evaluation, the examiner may not be certain whether the crying was caused by the high fever, stranger anxiety, or pain, or is indicative of a serious or localizing illness. Constant crying also makes portions of the physical examination, such as auscultation of the chest, more difficult. Before a repeat assessment is performed, efforts to make the child as comfortable as possible are indicated.

Febrile children can appear very ill, initially appearing listless, tachycardic, and tachypneic. These patients should receive antipyretic medications and be reassessed once they have defervesced. In the majority of children with uncomplicated viral illnesses, the vital signs normalize. Persistence of abnormal vital signs should prompt the clinician to further investigate the source of fever. Continued tachycardia and poor perfusion may be secondary to myocarditis. Tachypnea may be the sole symptom in patients with pneumonia, especially in children whose chief complaint is abdominal pain due to lower lobe pneumonia. Persistent irritability suggests meningitis/encephalitis.

**RISK FACTORS**

The sensitivity of the carefully performed clinical assessment, observation, history, and physical examination for the presence of serious illness is approximately 90%. If a serious illness is suspected, other data should be sought to improve this sensitivity level. Important supplemental data are age, body temperature, and the results of screening laboratory tests as indicated. Febrile children in the first 3 mo of life have yet to achieve immunologic maturity and therefore are more susceptible to severe infections. Thus, the febrile infant is at greater risk for serious bacterial infection than the child beyond 3 mo of age and warrants careful evaluation. Data from the era before widespread immunization for *H. influenzae* type b and pneumococcus suggest the risk of bacteremia in infants increases as the magnitude of fever increases; it is unclear how this applies today.

Screening laboratory tests may be helpful in identifying the febrile child at increased risk for selected serious illnesses. Practice guidelines from the prevaccine era suggested that white blood cell count might be useful in establishing a higher risk of bacteremia. Because the incidence of occult pneumococcal bacteremia in febrile children has declined significantly as a result of the introduction of conjugated pneumococcal vaccine, the utility of white blood cell count in otherwise healthy febrile young children older than 2–3 mo of age is questionable. Urinalysis and urine culture must always be considered when the source of fever is not apparent, especially in the highest-risk groups: females and uncircumcised males younger than 2 yr of age and all boys younger than 1 yr of age. The presence of leukocyte esterase, >5 white blood cells/high-power field on a spun urine specimen, or bacteria detected by Gram stain on an unspun urine specimen suggests urinary tract infection, but the sensitivity of these indicators is, on average, only 75–85%; urine culture is the definitive test. Procalcitonin, C-reactive protein, and interleukin-6 are being investigated as potential biomarkers of differentiating serious bacterial illness from benign viral disease in children.

**MANAGEMENT**

Most patients who present to the pediatrician’s office with an acute illness will not require resuscitation. However, the pediatrician needs to be prepared to evaluate and begin resuscitation for the seriously ill or unstable child. The pediatrician’s office should be stocked with appropriate equipment necessary to stabilize an acutely ill child. Maintenance of that equipment and ongoing training of the office staff in use of the equipment and procedures is required (see Chapter 66). The evaluation must begin with assessment of the ABCs—airway, breathing, and circulation. When assessing the airway, chest rise should be evaluated, and evidence of increased work of breathing sought. The examiner should ensure that the trachea is midline. If the airway is patent and no signs of airway obstruction are present, the patient is allowed to assume a position of comfort. If the child shows signs of airway obstruction, repositioning of the head with the chin-lift maneuver may alleviate the obstruction. An oral or nasal airway may be necessary in patients in whom airway patency cannot be maintained. These devices are not well-tolerated in conscious patients and may induce gagging or vomiting, and instead are most often utilized to facilitate effective bag-valve-mask ventilation. Once airway patency has been established, the adequacy of breathing should be evaluated. Slow respiratory rates or cyanosis may signal respiratory failure. If the airway is patent but the child’s respiratory effort is inadequate, positive pressure ventilation via bag-valve-mask should be initiated. Oxygen should be administered to all seriously ill or hypoxic children via nasal cannula or face mask. Auscultation of the lung fields should assess for air entry, symmetry of breath sounds, and presence of adventitious breath sounds such as crackles or wheezes. Bronchodilator therapy can be initiated to alleviate bronchospasm. Racemic epinephrine is indicated for stridor at rest in a patient with croup. Once airway and breathing have been addressed, circulation must be evaluated. This involves assessment of cardiac output. Symptoms of shock include tachycardia, cool extremities, delayed capillary refill time, mottled or pale skin, and effortless tachypnea. Hypotension is a late finding in shock and indicates significant decompensation has already taken place.

Vascular access is necessary for volume resuscitation in patients with impaired circulation, and an intraosseous line should be considered early on if there is any difficulty in vascular access for a patient requiring resuscitation. Once an intervention is performed, the clinician must reassess the patient.

If the febrile child is older than 3 mo and appears well, if the history or physical examination does not suggest a serious illness, the child may be followed expectantly. This profile applies to most children with acute febrile illnesses. If, on the other hand, the child appears ill, or the history or physical examination suggests a serious infection, definitive laboratory tests appropriate for those findings are indicated (chest x-ray for a child with grunting). If advanced imaging is required (ultrasound or CT scan for suspected appendicitis), it may be prudent to defer such testing to pediatric specialty care if the decision has already been made to transport the child to a higher level of care. The area of greatest controversy is whether laboratory studies are needed in a febrile child who appears well and has no abnormalities on history and physical examination, but who is younger than 3 mo or whose temperature is high. Many would agree that a sepsis work-up is indicated in the febrile child younger than 1 mo and possibly in the febrile child who is as old as 3 mo.

**DISPOSITION**

The majority of children evaluated in the office for an acute illness can be managed on an outpatient basis. These patients should have reassuring physical examinations, stable vital signs, and adequate follow-up. A mildly dehydrated patient can be discharged to home for a trial of oral rehydration. Patients with a respiratory illness who are exhibiting signs of mild respiratory distress may be monitored at home with a repeat examination scheduled for the next day. Depending on the child’s status, the comfort of the parents, and the relationship of the family with the physician, telephone follow-up may be all that is necessary.

If the physician feels comfortable in following as an outpatient the child in whom no specific diagnosis has been established, a follow-up examination may yield the diagnosis. During the initial visit, or from one visit to the next during the acute illness, the change in symptoms or in the findings on physical examination over time may provide important diagnostic clues. For the child in whom a diagnosis has already been established and who does not require hospitalization, follow-up by telephone or an office visit should be used to monitor the course of the illness and to further educate and support the parents.

However, if it is deemed that the child needs a higher level of care, it is the pediatrician’s responsibility to decide what method of transfer is appropriate. Physicians may be reluctant to call for help because of a misperception that 911 services should be activated only for full-blown resuscitations. Emergency Medical Services (EMS) transport should be initiated for any child who is physiologically unstable (e.g., with severe respiratory distress, hypoxia, signs of shock, or altered mental status). If the family’s ability to comply promptly with
recommendation for emergency department evaluation is in question, that patient should also be transported by EMS. Some physicians and families may defer calling EMS because of the perception that a parent can get to the hospital faster by private car. Although rapidity of transport should be considered, the need for further interventions during transport and the risk of clinical decompensation are other important factors in the decision to activate EMS. Ultimately, the legal responsibility for choosing an appropriate level of transport for a patient lies with the referring physician, until responsibility of care is officially transferred to another medical provider.

*Bibliography is available at Expert Consult.*
Bibliography

The overwhelming majority of the 30 million children who present annually for emergency care in the United States are seen at community hospital emergency departments (EDs). Visits to children's hospital EDs account for just 11% of initial emergency care encounters. This distribution suggests that the greatest opportunity to optimize care for acutely ill or injured pediatric patients, on a population basis, occurs broadly as part of a systems-based approach to emergency services, an approach that incorporates the unique needs of children at every level. Conceptually, emergency medical services for children are characterized by an integrated, continuum of care model (Fig. 66-1). The model is designed such that patient care flows seamlessly from the primary care medical home through transport and on to hospital-based definitive care. It includes the following 5 principal domains of activity:

1. Prevention, primary and secondary
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: ED and inpatient
4. Interfacility transport, as necessary, for definitive or subspecialty care (see Chapter 66.1)
5. Rehabilitation.

The federal Emergency Medical Services for Children (EMSC) program of the Health Resources and Services Administration's Maternal and Child Health Bureau has stewarded improvements in the care of children in the context of the continuum of care model. The programmatic mission of the EMSC program is as follows:

- To ensure state-of-the-art emergency medical care for the ill or injured child and adolescent.
- To ensure that pediatric services are well integrated into an emergency medical services system and backed by optimal resources.
- To ensure that the entire spectrum of emergency services—including primary prevention of illness and injury, acute care, and rehabilitation—is provided to infants, children, adolescents, and young adults.

EMSC funding to states and U.S. territories has created a national framework upon which necessary advances in education, advocacy, and research are taking place. EMSC grantees, constituents, and stakeholders as well as professional organizations such as the American Academy of Pediatrics are collaboratively engaged in implementation activities and projects that address the pediatric-specific recommendations stemming from the Institute of Medicine (IOM) report The Future of Emergency Care in the United States Health System.

**THE PRIMARY CARE PHYSICIAN AND OFFICE PREPAREDNESS**

The primary care physician (PCP) has multiple important roles in the emergency medical services system. Through anticipatory guidance, the PCP can help shape the attitudes, knowledge, and behaviors of parent and child, with the primary goal of preventing acute medical events, such as injury and status asthmaticus. The point of care initiation for many acute problems is often the PCP office. From the standpoint of personnel, equipment, training, and protocols, the PCP office setting must be adequately prepared to initially manage acute and emergency exacerbations of common pediatric conditions, such as respiratory distress and seizures. Furthermore, on rare occasion, the PCP office environment may be confronted with a child in clinical extremis who requires resuscitative intervention and stabilization. It is, therefore, incumbent upon the PCP not only to ensure access to emergency medical services (EMS), that is, 911 system activation, but also to ensure that there is adequate, onsite psychomotor skill preparation to deal with such an emergency. Office preparedness requires training and continuing education for staff members, protocols for emergency intervention, ready availability of appropriate resuscitation drugs and equipment, and knowledge of local EMS resources and ED capabilities.

**Staff Training and Continuing Education**

It is a reasonable expectation that all office staff, including receptionists and medical assistants, be trained in cardiopulmonary resuscitation (CPR) and that their certification be maintained on an annual basis. Nurses and physicians should also have training in a systematic approach to pediatric resuscitation. Core knowledge may be obtained through standardized courses in advanced life support (ALS) offered by national medical associations and professional organizations. Frequent recertification is important for knowledge retention and skill maintenance. Examples are the Pediatric Advanced Life Support (PALS) and Pediatric Emergency Assessment, Recognition and Stabilization (PEARS) courses sponsored by the American Heart Association, the Advanced Pediatric Life Support (APLS) course sponsored by the American Academy of Pediatrics (AAP) and the American
Protocols
Standardized protocols for telephone triage of seriously ill or injured children are essential. When a child's status is in question and prehospital care is available, ambulance transport in the care of trained personnel is always preferable to transport by privately owned vehicle. This obviates the potentially serious medical consequences of relying on unskilled and distraught parents without the ability to provide even basic life support (BLS) measures to an unstable child during transport to an ED. Practitioners can work with their local pediatric emergency care resource center (e.g., children's hospital or academic department of pediatrics) to develop and maintain written protocols for office-based management of a range of conditions, including anaphylaxis, cardiopulmonary arrest, head trauma, ingestions, shock, status asthmaticus, status epilepticus, and upper airway obstruction. Regular practice using mock code scenarios improves office-based practitioner confidence and self-efficacy in managing these problems.

Resuscitation Equipment
Availability of necessary equipment is a vital part of an emergency response. Every physician's office should have essential resuscitation equipment and medications packaged in a pediatric resuscitation cart or kit (Table 66-1). This cart or kit should be checked on a regular basis and kept in an accessible location known to all office staff. Outdated medications, a laryngoscope with a failed light source, or an empty oxygen tank represents a potential catastrophe in a resuscitation scenario. Such an incident can be easily avoided if an equipment checklist and maintenance schedule are implemented. A pediatric kit that includes posters, laminated cards, or a color-coded length-based resuscitation tape specifying emergency drug doses and equipment size is invaluable in avoiding critical therapeutic errors during resuscitation.

To facilitate emergency response when a child needs rapid intervention in the office, all personnel should have designated roles. Organizing a "code team" within the office ensures that necessary equipment is made available to the physician in charge, that an appropriate medical record detailing all interventions and the child's response is generated, and that the 911 call for EMS response or a transport team is made in a timely fashion.

Transport
Once the child has been stabilized, a decision must be made on how to transport a child to a facility capable of providing definitive care. If a child has required airway or cardiovascular support, has altered mental status or unstable vital signs, or has significant potential to deteriorate en route, it is not appropriate to send the child via privately owned vehicle, regardless of proximity to a hospital. Even when an ambulance is called, it is the PCP's responsibility to initiate essential life support measures and to attempt to stabilize the child before transport.

In metropolitan centers with numerous public and private ambulance agencies, the PCP must be knowledgeable about the level of service that is provided by each. The availability of BLS versus ALS services, the configuration of the transport team, and pediatric expertise vary markedly among agencies and across jurisdictions. BLS services provide basic support of airway, breathing, and circulation, whereas ALS units are capable of providing resuscitation drugs and procedural interventions as well. Some communities may have only BLS services available, whereas others may have a 2-tiered system, providing both BLS and ALS. It may be appropriate to consider medical air transport when definitive or specialized care is not available within an immediate community or when ground transport times are prolonged. In that case, initial transport via ground to an appropriate helicopter landing zone or a local hospital for interval stabilization may be undertaken, pending arrival of the air transport team. Independent of whether a child is to be transported by air or ground, copies of the pertinent medical records and any radiologic studies or laboratory results should be sent with the patient, and a call made to the physicians at the receiving facility to alert them to the referral and any treatments administered. Such notification is not merely a courtesy; direct physician-to-physician communication is essential to ensure adequate transmission of patient care information, to allow

E, essential; S, strongly suggested.

mobilization of necessary resources in the ED, and to redirect the transport if the emergency physician believes that the child would be more optimally treated at a facility with specialized services.

**PEDICATRIC PREHOSPITAL CARE**

Prehospital care refers to emergency assistance rendered by trained emergency medical personnel before a child reaches a treating medical facility. The goals of prehospital care are to further minimize systemic insult or injury through a series of well-defined and appropriate interventions and to embrace principles that ensure patient safety. Most communities in the United States have a formalized EMS system; the organizational structure and nature of emergency medical response depend greatly on local demographics and population base. EMS may be provided by volunteers or career professionals working in a fire-based or independent “third service” response system. Key points to recognize in negotiation of the junction between the community physician and the local EMS system include access to the system, provider capability, and destination determination.

**Access to the EMS System**

Virtually all Americans have access to the 911 telephone service that provides direct access to a dispatcher who coordinates police, fire, and EMS responses. Some communities have an enhanced 911 system, in which the location of the caller is automatically provided to the dispatcher, permitting emergency response even if the caller, such as a young child, cannot give an address. The extent of medical training for these dispatchers varies among communities, as do the protocols by which they assign an emergency response level (BLS vs ALS). In some smaller communities, no coordinated dispatch exists, and emergency medical calls are handled by the local law enforcement agency.

When activating the 911 system, the physician must make clear to the dispatcher the nature of the medical emergency and the condition of the child. In many communities, emergency medical dispatchers are trained to ask a series of questions per protocol that determines the appropriate level of provider to be sent.

**Provider Capability**

There are many levels of training for prehospital EMS providers, ranging from individuals capable of providing only first aid to those trained and licensed to provide ALS. All EMS personnel, whether basic or emergency medical technicians (EMTs) or paramedics, receive training in pediatric emergencies; however, pediatric cases actually constitute roughly 10% of all EMS transports.

First responders may be law enforcement officers or firefighters, who are dispatched to provide emergency medical assistance, or bystanders. Public safety personnel have a minimum of 40 hr of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained personnel. In some smaller communities, this may be the only prehospital emergency medical response available.

In the United States, the bulk of emergency medical response is provided by EMTs, who may be volunteers or paid professionals. Basic EMTs may staff an ambulance after undergoing a training program of approximately 100 hr. They are licensed to provide BLS services but may receive further training in some jurisdictions to expand their scope of practice to include intravenous catheter placement and fluid administration, management of airway adjuncts, and the use of an automated external defibrillator.

Paramedics, or EMT-Ps, represent the highest level of EMT response, with medical training and supervised field experience of approximately 1,000 hr. Paramedic skills include advanced airway management, including endotracheal intubation; placement of peripheral, central, or intravenous lines; intravenous administration of drugs; administration of nebulized aerosols; needle thoracostomy; and cardioversion and defibrillation. These professionals provide ALS services, functioning out of an ambulance equipped as a mobile intensive care unit. In a joint policy statement entitled Equipment for Ground Ambulances, the AAP, the ACEP, the American College of Surgeons Committee on Trauma, EMSC, the ENA, the National Association of EMS Physicians, and the National Association of EMS Officials have published guideline standards for essential ambulance equipment, medications, and supplies necessary to provide BLS and ALS care across the age spectrum. This essential equipment list represents one of the reference standards that the federal EMSC program has adopted as a performance measure for state-level operational readiness to care for children in an EMS system.

Both basic EMTs and paramedics function under the delegated licensing authority of a supervisory EMS medical director. This physician or a group of prehospital practice is broadly characterized under the umbrella term medical control. Direct, or online, medical control refers to medical direction either at the scene or in real time via voice or video transmission. Indirect, or offline, medical control refers to the administering of medical direction prior to and after the provision of care. Offline activities, such as provider education and training, protocol development, and medical leadership of quality assurance/quality improvement programs, represent areas in need of greater pediatric input. As a measure of the degree to which EMSC permanence is being established in state EMS systems, the federal EMSC program has required demonstration of participation in online and offline medical direction activities for pediatric patients and the seating of an EMSC advisory committee at the state level. These advisory bodies are well positioned to support EMS agencies in their pediatric readiness as well as provide a forum for the active engagement of pediatric care experts at a system level.

**Destination Determination**

The destination to which a pediatric patient is transported may be defined by parental preference, provider preference, or jurisdictional protocol, which is typically predicated on field assessment of anatomic and physiologic criteria and, in the case of trauma, mechanism of injury. In communities served by an organized trauma or regionalized EMS system that incorporates pediatric designation based on objectively verified hospital capabilities, seriously ill or injured children may be triaged by protocol to the highest-level center reachable within a reasonable amount of time. The mantra is to deliver the child to the “right care in the right time,” even if it requires bypassing closer hospitals. An exception is the child in full arrest, for whom expeditious transport to the nearest facility is always warranted. In 2012, modification of the Centers for Disease Control and Prevention’s national field trauma triage guidelines included a refinement of age-specific vital sign assessment criteria to more accurately reflect the unique physiologic response to injury in children. The Centers for Disease Control and Prevention guidelines are a valuable resource for pediatricians involved in EMS medical direction and are accessible as a multipurpose toolkit, including an educational webinar and downloadable mobile application, at http://www.cdc.gov/fieldtriage.

Regionalization in the context of EMS is defined as a geographically organized system of services that ensures access to care at a level appropriate to patient needs while maintaining efficient use of available resources. This system concept is especially germane in the care of children, given the relative scarcity of facilities capable of managing the full range and scope of pediatric conditions (Fig. 66-2). Regionalized systems of care coordinated with emergency medical dispatch, field triage, and EMS transport have demonstrated efficacy in improving outcomes for pediatric trauma patients, especially for younger children and for children with isolated head injury. Emerging evidence also suggests a similar benefit conferred to children in shock identified in the field who are preferentially transported to hospital EDs with documented pediatric ALS capability. The existence of statewide or regional standardized systems that formally recognize hospitals able to stabilize and/or manage pediatric medical emergencies is another federal EMSC performance measure against which operational capacity to provide optimal pediatric emergency care in this country is currently being judged.

In communities that do not have a hospital with the equipment and personnel resources to provide definitive pediatric inpatient care, interfacility transport of a child to a regional center should be undertaken after initial stabilization (see Chapter 66.1). When interfacility
transport is to be undertaken, indications for transfer, parental consent for transfer, and acceptance of the patient by the receiving physician must all be clearly documented in the medical record.

The ability of hospital EDs to respond to the emergency care of children varies and depends on a number of factors in addition to availability of equipment and supplies. Training, awareness, and experience of the staff as well as access to pediatricians and medical and surgical subspecialists also play a key role. The majority of children who require emergency care are evaluated in community hospitals by physicians, nurses, and other healthcare providers with variable degrees of pediatric training and experience. Although children account for 25-30% of all ED visits, only a fraction of these encounters represent true emergencies. Because the volume of critical pediatric cases is low, emergency physicians and nurses working in community hospitals often have limited opportunity to reinforce their knowledge and skills in the assessment of ill or injured children and in pediatric resuscitation. General pediatricians from the community may be consulted when a seriously ill or injured child presents to the ED, and they should have a structured approach to the initial evaluation and treatment of an unstable child of any age, regardless of the underlying diagnosis. Early recognition of life-threatening abnormalities in oxygenation, ventilation, perfusion, and central nervous system function and rapid intervention to correct those abnormalities are key to successful resuscitation and stabilization of the pediatric patient.

In its report The Future of Emergency Care in the U.S. Health System, the IOM strongly recommended that hospitals and EMS systems appoint qualified coordinators for pediatric emergency care, a recommendation consistent with pediatric emergency readiness guidelines advocated by the AAP and ACEP. Only 18% of EDs in the United States currently appoint a physician coordinator, and 12% appoint a nursing coordinator for pediatric emergency care. EDs that do appoint these positions tend to be more prepared as measured by compliance with nationally published guidelines on the care of children in the ED.

Minimum standards must be met by community EDs to ensure that children receive the best emergency care possible. Updated guidelines for the care of children in the ED have been published, reaffirmed and are endorsed by the AAP, the ACEP, and the ENA. These guidelines provide current information on policies, procedures, protocols, quality assurance methods, and equipment and supplies considered essential for managing pediatric emergencies. Specific recommendations on equipment, supplies, and medications for the ED are listed and updates are available on the AAP website. Table 66-2 lists sample policies, procedures, and protocols specifically addressing the needs of children in the ED.

The way in which the family supports the child during a crisis and, consequently, how the family is supported in the ED when caring for the child are critical to patient recovery, family satisfaction, and

**Family-centered care, including:**
1. Involving families in patient care decision-making and in medication safety processes.
2. Family presence during all aspects of emergency care, including resuscitation.
3. Education of the patient, family, and regular caregivers.
4. Discharge planning and instruction.
5. Bereavement counseling.

**Communication with patient’s medical home or primary healthcare provider**

Medical imaging policies that address age- or weight-appropriate dosing for children receiving studies that impart ionizing radiation, consistent with ALARA (as low as reasonably achievable) principles

All-hazard disaster preparedness plan that addresses the following pediatric issues:
1. Availability of medications, vaccines, equipment, and appropriately trained providers for children in disasters.
2. Pediatric surge capacity for both injured and noninjured children.
3. Decontamination, isolation, and quarantine of families and children of all ages.
4. A plan that minimizes parent-child separation and includes system tracking of pediatric patients, allowing for the timely reunification of separated children with their families.
5. Access to specific medical and mental health therapies, as well as social services, for children in the event of a disaster.
6. Disaster drills, which should include a pediatric mass casualty incident at least every 2 yr.
7. Care of children with special healthcare needs.
8. A plan that includes evacuation of pediatric units and pediatric specialty units.

the mitigation of posttraumatic stress. Commitment to patient- and family-centered care in the ED ensures that the patient and family experience guides the practice of culturally sensitive care and promotes patient dignity, comfort, and autonomy. In the ED setting, particular issues, such as family presence, deserve specific attention. Surveys of parents have indicated that most want to be with their child during invasive procedures and even during resuscitation. Allowing their presence has been shown to reduce parental and patient anxiety and does not interfere with procedure performance. Patient- and family-centered care is also associated with improved care quality and patient safety.

EMERGING ISSUES IN EMSC

Of the pediatric-specific recommendations promulgated by the IOM in its widely publicized 2006 report on the future of emergency care, 3 have emerged as especially important for EMSC. The first deals directly with increased federal funding for the EMSC program, which supports more than 80 grantees with an established presence in 49 states, 5 U.S. territories, the District of Columbia, and the freely associated states of Micronesia, Palau, and the Marshall Islands. The grant awards cover 5 distinct funding categories ranging from basic science and clinical investigation to public sector capacity-building programs to national technical assistance centers to multicenter trials conducted within a large research network. Through the diversity of activity generated within the program, and in collaboration with stakeholders, the EMSC program affords synergistic opportunity to further the progress realized in the programs’ first 30 yr of existence. A tumultuous appropriations history not-with-standing, including several years of budget elimination, Congressional reauthorization, due in 2014, and will ensure stability for the EMSC program at least in the near term.

In addition to EMSC resource support, the IOM also recommended that (a) federal agencies in partnership with state and regional planning bodies and emergency care provider organizations convene a panel with multidisciplinary expertise to develop strategies for addressing pediatric needs in the event of a disaster, and (b) the U.S. Department of Health and Human Services conduct a study to examine the gaps and opportunities in emergency care research, including pediatric emergency care, and recommend a strategy for the optimal organization and funding of the research effort. Both of these recommendations have generated activity of significant import to the emergency care community, EMSC specifically, and warrant mention.

Disaster Preparedness

Children constitute approximately 30% of the population; in a catastrophic event, natural or human-made, several unique factors place children at disproportionate, increased risk. During the day large groups of children are typically cohorted, separate from their families, in schools and daycare centers where mass casualties can easily occur and reunification is challenging. Furthermore, in the event of a biologic or chemical attack, unique anatomic, developmental, and physiologic features make children especially vulnerable to absorption and/or inhalation of toxic agents. Following the broad pediatric impact of the devastating Gulf Coast hurricanes Katrina and Rita in the mid-2000s, Congress established the National Commission on Children and Disasters. The Commission’s mandate was to conduct a comprehensive study to examine and assess the needs of children as they relate to preparation for, mitigation of, response to, and recovery from all hazards, including major disasters and emergencies. The findings and recommendations of the Commission’s 2010 report to the President and to Congress have established a broad framework for ongoing preparedness efforts related not only to child physical health, but also, importantly, to behavioral and emotional well-being. In addition, pertinent resources related to pediatric-focused areas of concerns such as evacuation, separation-reunification, sheltering, countermeasures, surge capacity and triage are being monitored and chronicled under the PEDPrepared Disaster Clearinghouse at the EMSC National Resource Center website, http://www.emscnrc.org/pedprepared.

Bibliography is available at Expert Consult.

66.1 Interfacility Transport of the Seriously Ill or Injured Pediatric Patient

Elizabeth A. Edgerton and Bruce L. Klein*

Patients often seek treatment at facilities that lack sufficient expertise to treat their conditions, necessitating transfer to more appropriate specialty centers. This is especially pronounced in pediatrics. EMS providers or parents usually take children to local EDs first, where their conditions and physiologic stabilities are assessed. Although bringing a child directly to the local ED may be proper logistically, local EDs can be less than ideal for pediatric emergencies. Children account for 27% of all ED visits but only 6% of EDs have all the necessary supplies for pediatric emergencies. Also, general EDs are less likely to have pediatric expertise or policies in place for the care of children. Outcomes for critically ill children treated in pediatric intensive care units (PICUs) are better than for those treated in adult ICUs. When pediatric critical care is required, transport to a regional PICU is indicated. In addition, often the type of subspecialty care needed (e.g., pediatric orthopedics) is available only at the pediatric center.

Pediatric transport medicine consists of the interfacility transfer of infants, children, and adolescents from community facilities to pediatric centers that can provide the needed level of expertise. Transport is performed by professionals proficient in pediatric transport on specially age-equipped ground, rotorcraft, or fixed-wing ambulances. Pediatric transport medicine is a multidisciplinary field comprising pediatric critical care and pediatric emergency medicine physicians (and, sometimes for very young infants, neonatologists); nurses, respiratory therapists, and paramedics with advanced training for pediatric transport; and communications specialists. The goal is to deliver quality pediatric care to the region’s children, while optimizing the use of regional resources. For the individual child, the aim is to stabilize and, when appropriate, begin treating as soon as possible—that is, at the local ED and during transport, well before arrival at the referral center.

The AAP Section on Transport Medicine, the Association of Air Medical Services, the Federal Aviation Administration (FAA), and others have published recommendations regarding transport programs. Models for pediatric transport services vary depending on the needs and available resources in a geographic region, but all should have certain basic components: a network of community hospitals and regional pediatric centers; an established communications and dispatch system that easily facilitates transfer to the pediatric center; ground and/or air ambulances; medical and nursing leadership from pediatric critical care or pediatric emergency medicine (or neonatology); experienced pediatric medical control physicians (MCPs); a multidisciplinary team of pediatric transport professionals specially trained to provide the appropriate level of care required during transport; operational and clinical policies and procedures that guarantee safe, state-of-the-art, and timely pediatric critical care transport; and a database for quality and performance assessment.

COMMUNICATIONS AND DISPATCH CENTER

Communications are one of the most vital components of a regional transport system. Treating a critically ill or injured child is an uncommon event for most community physicians. Therefore, they need to know whom, how, and when to call for assistance in the stabilization and transfer of a pediatric patient. The communications and dispatch center provides a single telephone number for such calls.

The communications and dispatch center coordinates communications among the outlying facility, receiving unit, MCP, transport team, and others. This center may be part of a hospital unit (e.g., ED, PICU), self-contained in a single institution (e.g., Emergency Communications and Information Center), or based offsite as a freestanding center coordinating communications and dispatch for multiple transport programs.

Staffing varies depending on the type of center. On-duty nurses or physicians may receive calls at unit-based models with low volumes.

*Adapted initially from Dr. Lorry R. Frankel's chapter in the 18th edition of this book.
Bibliography

American Academy of Pediatrics; American College of Emergency Physicians; American College of Surgeons, Committee on Trauma; Emergency Medical Services for Children; Emergency Nurses Association; National Association of EMS Physicians; National Association of State EMS Officials: Joint policy statement—equipment for ground ambulances, Prehosp Emerg Care 18:92–97, 2014.

In contrast, dedicated communications specialists usually staff self-contained or freestanding centers, which tend to be busier. The communications specialist has numerous responsibilities, including answering the referring physician's call promptly; documenting essential patient demographic information; arranging for immediate consultation with the MCP; dispatching the transport team to the referring facility expeditiously; updating the referring facility with any changes in the arrival time; and coordinating medical control and other necessary transport-related calls. The transport team must be equipped with a cellular telephone or radio for immediate contact with the referring and referring facilities.

**MEDICAL CONTROL PHYSICIAN**

The MCP is involved in the clinical care and safe transport of the patient from the time of referral through arrival at the receiving hospital unit. The MCP's oversight increases once the transport team arrives at the referring facility. The MCP should have expertise in pediatric critical care or pediatric emergency medicine (or sometimes neonatology). Besides having the knowledge required to stabilize a critically ill or injured child, the MCP must be familiar with the transport environment; the transport team members’ capabilities; the program's policies and procedures; and the region's geography, medical resources, and regulations regarding interhospital transport. The MCP must possess good interpersonal and communication skills and must be able to maintain collegiality with the referring hospital's staff during a potentially difficult and stressful situation.

Once a transport call is received, the MCP must be immediately available to confer with the referring physician. Although the MCP may have other responsibilities, these transport responsibilities take priority in order to avoid undue delays when transferring a critically ill child. Often the MCP recommends further testing or therapeutic interventions that can be delivered by the referring hospital before the transport team arrives. The MCP may seek additional guidance from other specialists, as necessary. Because the child's condition may change rapidly, the MCP must remain ready to give additional advice. All conversations and recommendations regarding the care of the patient should be documented. Some centers record these conversations.

After discussion with the referring physician—and, when warranted, with the transport staff—the MCP determines the best team composition and vehicle for transport. The MCP usually does not accompany the team but remains available, by phone or radio, to supervise care.

**TRANSPORT TEAM**

Transport team composition varies among programs—and sometimes within an individual program. The team's composition is based on a variety of factors, including the severity of the child's illness or injury; the distance to the referring facility; the team members' advanced practice abilities; the referrer's (reasonable or unreasonable) insistence that a physician be present; the program's historical professional makeup; and the region's staffing regulations. The team should be composed of physicians, nurses, respiratory therapists, and/or paramedics who have expertise in pediatric critical care or pediatric emergency medicine (or neonatology in some cases), as well as advanced education and training in those cognitive and procedural areas important for pediatric critical care transport. There is a lower incidence of transport-related morbidity for critically ill and injured children transported by pediatric specialty teams than for those transported by generalist teams.

Various scoring systems have been developed to predict the need for a physician during transport. It seems that a team member’s training, experience, and skill in treating critically ill patients are more important considerations than that team member’s professional degree. Team members must understand basic pediatric pathophysiology and collectively must be able to assess and monitor a critically ill or injured child; manage the airway and provide respiratory support; obtain vascular access; perform point-of-care testing; and administer those medications commonly used in pediatric critical care transport. They must be familiar with the physiologic alterations as well as practical difficulties of the transport environment and, importantly, must be comfortable working in an out-of-hospital setting. Physicians are less often deployed on transport teams in part because of the advanced training that other healthcare professionals on the transport team receive.

The transport team should have a designated team leader who, in addition to the team leader's many other responsibilities, interacts with the MCP during the transport. Once the team arrives at the referring facility, the team should reassess the child’s condition, review all of the pertinent diagnostic studies and therapies, and discuss the situation with the referring staff and parents. If the patient's condition has changed significantly, the team leader may need to contact the MCP for additional advice. Otherwise, the team leader should generally notify the MCP before starting to bring the child to the receiving facility. Any care delivered by the team during transport should be documented, and copies of all medical records—including laboratory data, radiographs, and scans—should accompany the child to the pediatric center. The receiving unit must be updated prior to arrival so it can finalize preparations for the patient.

**GROUND VERSUS AIR AMBULANCE**

Transport options include ground, rotorcraft, and fixed-wing ambulances. Vehicle selection depends on the child's emergency needs; transport team's capabilities; any out-of-hospital staffing or equipment requirements (e.g., for extracorporeal membrane oxygenation, inhaled nitric oxide or heliox); referring facility's abilities; distance; terrain; traffic patterns; ground or air ambulance availability; helicopter landing pad or airport access; weather conditions; and expense.

The transport vehicle must be equipped with electrical power, oxygen, and suction and must have sufficient space for the equipment and supplies that the team brings along—stretcher or isolette, monitor, ventilator, oxygen tank(s), medication pack(s), infusion pumps, and more. Compared with helicopters, ambulances are more spacious and able to carry more weight, so they can accommodate larger teams and more equipment. Another advantage of ground ambulance transport is the ability to stop en route if the patient’s condition deteriorates; this feature greatly facilitates the performance of certain interventions, such as intubation.

An airplane may be able to fly to an area where distance (>150 miles), altitude, or weather precludes helicopter use. However, the use of an airplane necessitates several ambulance transfers, with their attendant delays and potential complications. There are also delays when the plane must fly from a remote base to the program’s jurisdiction.

**TRANSPORT PHYSIOLOGY**

When possible, the transport team tries to provide the same care during transport as the patient would receive in the specialty center. This can be difficult, though, because of limitations in personnel, equipment, and space, as well as other environmental challenges.

The team and child are subjected to variable intensities of background noise and vibration while traveling in the vehicle cabin. Noise can impair the team’s ability to auscultate breath sounds, heart sounds, and blood pressure, another reason for monitoring vital signs mechanically and relying on other assessment modalities, such as the level of mentation, skin color, and capillary refill. To mitigate noise, the helicopter crew and patient should wear helmets or headphones (or another wearable noise attenuator such as MiniMuffs [Natus Medical Incorporated, San Carlos, CA]). Motion and vibration can lead to increased metabolic rate, shortness of breath, and fatigue in the patient, as well as motion sickness in the patient and staff.

On fixed- or certain rotary-wing transports, the patient may suffer adverse physiologic effects from altitude. With increasing altitude, the barometric (atmospheric) pressure decreases and gases expand. As the barometric pressure drops and gas expands, the partial pressures of ambient oxygen (P\text{O}_2) and, consequently, arterial oxygen (P\text{A}_O_2) decrease. For example, at 8,000 feet—an elevation at which unpressurized airplanes may fly, as well as the effective cabin altitude for many pressurized airplanes flying at 35,000 to 40,000 feet—the barometric pressure, P\text{O}_2, P\text{A}_O_2, and arterial oxygen saturation fall to 565 mm Hg, 118 mm Hg, 61 mm Hg, and 93%, respectively. (In comparison, the barometric pressure, P\text{O}_2, P\text{A}_O_2, and arterial oxygen saturation are...
760 mm Hg, 159 mm Hg, 95 mm Hg, and 100% at sea level.) Although healthy individuals usually tolerate these changes well, patients with respiratory insufficiency, significant blood loss, or shock may decompensate and should receive supplemental oxygen.

Gases expand 10-15% at the few thousand feet at which helicopters typically fly, and approximately 30% at 8,000 feet. Gases within the body itself also expand as the altitude increases. Gas expansion must be appreciated during transport via air of a patient with a pneumocephalus, pneumothorax, bowel obstruction, or another condition involving entrapped gas. Prior to transport, a pneumothorax should be decompressed, and a nasogastric tube inserted for ileus.

SAFETY
Safety is of paramount importance and mandates constant vigilance by everyone involved. Accident rates for pediatric air and ground transport are estimated at approximately 1/1,000 transports. The team should routinely attend pilot briefs, as well as perform safety inspections of the vehicles and equipment, aided by checklists. When in doubt, the MCP should solicit input from the staff about whether to transport via air or ground ambulance or to employ lights and sirens, decisions that cannot be taken lightly. The pilot’s or driver’s judgment as to the safety of proceeding during inclement weather or with a mechanical problem must not be overruled.

Organizations, such as the FAA and the National Transportation Safety Board, play a role in ensuring safe interfacility transport. The Commission on Accreditation of Medical Transport Systems (CAMTS) is an independent, peer review organization that was established in 1990 in response to the number of air medical accidents in the 1980s. CAMTS, through voluntary participation, audits and accredits fixed-wing, rotary-wing, and ground interfacility medical transport services.

FAMILY-CENTERED CARE
Family-centered care represents a philosophy that respects the important role that family members play in a child’s care. It recognizes family members and healthcare providers as partners in caring for the child. Family presence during transport is beneficial because it provides support to children in stressful situations and assists healthcare providers in delivering care to patients with complex and/or chronic medical problems.

As care is transitioned from the referring hospital, it is the transport team’s responsibility to maintain family-centered care. The team meets with family members to explain the transport process, obtain consent, and discuss anticipated management. When possible, the transport team should attempt to accommodate a family member’s presence onboard. However, the family member and child may need to be separated when the child is critically ill and rapid transport is essential, or if there is space or weight limitations in the air or ground ambulance. In these situations, it is important that family members have a clear understanding of how the child will be cared for during the separation.

REFERRING HOSPITAL RESPONSIBILITIES
Transfer of a patient to another facility requires written documentation by the referring physician of the need and reasons for transfer, including a statement that the risks and benefits, as well as any alternatives, have been discussed with the parents. The parent’s informed consent to the transfer should be obtained.

Federal law under the Emergency Medical Treatment and Active Labor Act (EMTALA), part of the Consolidated Omnibus Budget Reconciliation Act (COBRA), imposes specific requirements that a patient presenting to an ED be given a medical screening examination without regard to ability to pay. If upon examination an emergency medical condition is found, the hospital is required to stabilize the patient or to transfer the patient to another facility if unable to stabilize the patient or if requested by the patient. The primary requirement is that the referring physician must certify that the medical risks of transfer are outweighed by its potential benefits. The receiving hospital must agree to accept the patient and have the space and staff to provide the necessary treatment. The transferring hospital is responsible for arranging for the transfer and ensuring that it is performed by qualified medical personnel with appropriate equipment. It must send copies of the patient’s medical records and test results, even those that become available after the transfer is complete.

Some referring hospitals have entered into transfer agreements with specialty centers in the interests of facilitating the smooth and safe transfer of the pediatric patient. Having prepared forms for all of the above purposes also aids in the transfer process.

Each hospital needs to review its facility’s guidelines, and if established guidelines do not exist the EMSG, in partnership with the Emergency Nurses Association and the Society of Trauma Nurses, has developed the “Inter Facility Transfer Tool Kit for the Pediatric Patient” (available at www.pediatricreadiness.org). This tool kit includes the essentials for comprehensively and safely transferring the pediatric patient to the most appropriate level of care in a timely manner.

EDUCATIONAL OUTREACH
Besides safe and rapid transport, regional pediatric transport programs (and their specialty centers) have an obligation to provide educational opportunities to community healthcare providers so that these providers can acquire the necessary skills to evaluate and stabilize a critically ill or injured child until the transport team arrives. These learning activities may include transport case reviews; lectures on pediatric acute care topics; resuscitation programs such as the PALS course, APLS course, and S.T.A.B.L.E. (sugar and safe care, temperature, airway, blood pressure, lab work, emotional support) program; and rotations through the specialty center’s pediatric ED and PICU. These activities also help cement relationships with the referring facility’s staff.

66.2 Outcomes and Risk Adjustment
Evaline A. Alessandrini

Health services research has documented wide variation in the likelihood that patients receive quality, evidence-based healthcare, and this can negatively impact the health of children and youth. The complexities of delivering high-quality healthcare are magnified in the ED. Patients are in crisis, EDs are often overcrowded, patient–physician relationships are based on brief interactions, and the variety of complaints and diagnoses is immense.

OUTCOME MEASURES IN EMERGENCY MEDICAL SERVICES FOR CHILDREN
Emergency Care for Children: Growing Pains, one report of the 2007 IOM series on the future of emergency care, recommends that pediatric emergency medical systems specifically support the development of national standards for emergency care performance measurement. The Donabedian structure–process–outcome model has set the framework for most contemporary quality measurement and improvement activities. Structural elements provide indirect quality-of-care measures related to a physical setting and resources. Process indicators provide a measure of the quality of care and services by evaluating the method or process by which care is delivered, including both technical and interpersonal components. Outcome elements describe valued results related to lengthening life, relieving pain, reducing disabilities, and satisfying the consumer.

Defining relevant outcomes for pediatric emergency care is difficult. A true “outcome-based” approach describes observable measures such as mortality, risk of organ system failure, and disability. An alternative approach is a “resource-based” outcome measure definition related to the level of care required. Children who are more ill, in general, require more resources. Thus, resource use across groups of patients reflects relative severity of illness in the groups. Examples of resource-based outcomes include need for hospital admission (ED disposition), ED
Bibliography

**Table 66-3** Stakeholder-Endorsed Outcome Measures for Pediatric Emergency Care

- Overall patient satisfaction with ED visit—nurses
- Overall patient satisfaction with ED visit—physicians
- Parent/caregiver understanding of ED discharge instructions
- ED length of stay for patients <18 yr of age
- Percentage of patients <18 yr of age left without being seen (LWBS)
- Effective pediatric procedural sedation
- Acute fracture patients with documented reduction in pain within 90 min of ED arrival
- Improvement in asthma severity score for patients with acute exacerbations
- ED revisit within 48 hr resulting in admission
- Medication error rates
- Global sentinel never events
- Unplanned return visit within 72 hr for the same/related asthma exacerbation
- Failure to achieve seizure control within 30 min of ED arrival
- Return visits within 48 hr resulting in admission for all urgent and emergency patients

**Table 66-4** Elements of the PRISA II Score

- Age <90 days
- Minor injury
- Abdominal pain in an adolescent
- Immunodeficiency
- Indwelling medical device
- Controller asthma medication
- Referral status
- Temperature
- Decreased mental status
- Low systolic blood pressure (<70 neonates and infants; <83 children; <100 adolescents)
- High diastolic blood pressure (>59 neonates and infants; >70, children; >90 adolescents)
- Low serum bicarbonate value (<20 mEq/L)
- High potassium value (>4.9 mEq/L)
- High blood urea nitrogen value (>80 mg/dL)
- High white blood cell count (>20,000/mm³)
- Oxygen therapy other than during inhaled bronchodilator treatments
- Low bicarbonate and high potassium values

**Table 66-5** Elements of the RePEAT Score

- Age
- Chief complaint
- Triage category
- Current use of prescription medications
- Arrival via EMS (ground/air)
- Heart rate
- Respiratory rate
- Temperature

length of stay, costs, and diagnostic and therapeutic interventions performed in the ED. Table 66-3 provides a list of outcome measures for pediatric emergency care developed by EMSC stakeholders during 2 separate consensus meetings.

**RISK ADJUSTMENT**

Measuring outcomes offers opportunities for EDs and other components of the healthcare system to make effective improvements over time, benchmark, and compare their end results with those of other institutions. Meaningful comparisons between EDs or within an ED over time generally require risk adjustment, which accounts for patient-related attributes such as age, or for preexisting conditions associated with the outcome of interest. Risk-adjustment “levels the playing field,” so that comparison of outcomes is as fair and meaningful as possible. Because children present to EDs with illnesses of varying acuity, ranging from rashes and colds to cardiac arrest, there is an inextricable linkage of severity to outcomes. Severity typifies the concept of “risk”—the higher the severity, the higher the risk of a given outcome. Without risk adjustment, EDs with sicker patients may appear to have worse outcomes.

A large number of instruments have been developed to adjust for severity or risk in clinical research and quality improvement activities. The commonly used PRISM (Pediatric Risk of Mortality) score is not well-suited for EMSC, given the extremely low rate of mortality. Several disease-specific acuity scoring systems are available for use in EMSC. The majority of these are intended for use in trauma patients, including the Injury Severity Score, Trauma Score, and Pediatric Trauma Score.

**RISK ADJUSTMENT TOOLS IN EMSC**

The choice of a risk-adjustment tool depends on several factors, including the population under study, the setting, and the outcomes of interest. Two risk-adjustment tools have been developed specifically for pediatric emergency medicine, the second-generation Pediatric Risk of Admission (PRISA II) score and the Revised Pediatric Emergency Assessment Tool (RePEAT).

**Pediatric Risk of Admission II**

PRISA II uses components of acute and chronic medical history and physiology to determine the probability of hospitalization. The outcome measure of interest is mandatory hospital admission (admissions utilizing therapies best delivered on an inpatient basis). Table 66-4 lists the patient-related attributes contributing to the PRISA II risk-adjustment score. Analytic models including the PRISA II score have good calibration (how well the probabilities predicted from the model correlated with the observed outcomes in the population) and discrimination (the ability to categorize subjects correctly into the categories of interest) with respect to mandatory hospital admission. Construct validity of the PRISA score was demonstrated by measuring the rates of the secondary outcomes: mandatory admission, PICU admission, and mortality. As the probability of hospital admission rose, the proportion of patients with these increasing care requirements also increased. This finding strongly supports the use of the PRISA II score as a valid measure of severity of illness. In addition, PRISA II was found to demonstrate racial/ethnic differences in severity-adjusted hospitalization rates, and also demonstrated that teaching hospitals had higher than expected severity-adjusted admission rates in comparison with non-teaching hospitals.

**Revised Pediatric Emergency Assessment Tool**

The RePEAT uses a limited set of data collected at the time of triage to model severity of illness as reflected by the level of care provided in the ED. This tool was developed to predict the level of care provided—routine assessment (clinical examination only ± nonprescription medicine), specific ED care (ED diagnostics and/or therapeutics), or hospital admission—with the implicit assumption that patients with a higher level of care have a higher severity of illness. Table 66-5 lists the patient-related attributes contributing to the RePEAT risk-adjustment score. As with the PRISA II score, analytic models including the RePEAT score have good calibration and discrimination with respect to predicting ED care and hospital admission. Furthermore, analytic models that compare costs and ED length of stay between EDs are improved by adjustment for severity of illness using the RePEAT score. These results demonstrate that RePEAT is a reasonable marker of severity of illness and that inclusion of this severity index substantially improves the ability to compare outcomes between EDs.

Institute of Medicine: To err is human: building a safer health care system, Washington, DC, 2000, National Academy Press.

International pediatric emergency medicine is an emerging academic field whose practitioners are committed to international collaboration aimed at improving the quality of care for children outside their national borders (Table 66-6).

Many models currently exist for the delivery of emergency care. The triage officer model is one in which a practitioner who works in an ED briefly provides intake for all patients and calls specialists to provide definitive care depending on the nature of the presenting complaint. The multiple physician model describes a scenario in which patients are divided by their chief complaints into medical, surgical, and pediatric groups. The field of emergency medicine provides a specialist skilled in the recognition, stabilization, and definitive treatment of a wide variety of acute illnesses and injuries. This approach to managing an emergency center is more efficient, relies less heavily on specialist availability, and requires fewer highly trained practitioners to operate. Children and adolescents constitute a subpopulation of emergency patients that deserves special attention because of pediatric-specific conditions, unique anatomy and physiology, developmental staging, and parental interactions.

The maturity of pediatric emergency medicine (PEM) in any given area depends on the healthcare priorities and resources of that geographic or physical setting. The places in which emergency care takes place range from the community (for those with no access to organized medical care) to state-of-the-art pediatric EDs in populated centers. The scope ranges from care of the individual patient to the management of populations of children involved in large-scale disasters. Barriers to quality care are different in each situation and in each part of the world, with the implication for the astute international PEM practitioner that solutions must be targeted to the local context of healthcare within a given environment.

**EMSC AND THE CONTINUUM OF CARE MODEL**

EMSC is a U.S. federal initiative designed to reduce child and youth disability and death as a result of severe illness or injury. The EMSC program has developed an operational framework for conceptualizing a systems approach to emergency care for children, known as the *continuum of care model*. The model specifically refers to the seamless care of ill and injured children from the community and medical home through to definitive care and return to the community. It has the following 5 principal components:

1. Prevention
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: emergency center and inpatient unit
4. Interfacility transport, as necessary, for definitive or subspecialty care (see Chapter 66.1)
5. Rehabilitation

This framework can also be applied to discussion of emergency care for children on a global level. With medical infrastructures that may not be consistent or well-organized, or that have been weakened by civil strife, natural disasters, and economic loss, the focus of child health in the developing world has been on prevention and acute care.

**APPLYING THE CONTINUUM OF CARE MODEL TO THE DEVELOPING WORLD**

### Prevention

**Infectious Diseases**

International child health has focused mainly on reducing preventable childhood illnesses, primarily through immunizations. Enormous advances have been realized in measles, neonatal tetanus, and polio reduction; wild-type smallpox was eradicated in 1978. Although there are advocates for providing primary care interventions (e.g., vaccinations) in the ED, the role of the PEM practitioner in this area of prevention has been limited.

### Injuries

Injuries are a leading cause of childhood morbidity and mortality. Unintentional injuries constitute 90% of injury mortality to children ages 5–19 yr and are the cause of 9% of the world’s mortality. Intentional injuries, an underrecognized and underreported phenomenon primarily for cultural reasons, make a smaller but significant contribution. Unintentional injuries cause more than 2,000 childhood deaths daily or 950,000 annually worldwide. The burden of these deaths is borne disproportionately by children in middle- and lower-income countries.
countries, where more than 95% of all injury deaths occur. For each of these deaths, many more children are permanently disabled and an even larger number are treated and released without permanent sequelae.

The World Health Organization (WHO) and United Nations Children's Fund (UNICEF) have outlined several proven injury prevention strategies of which child health practitioners in the global community must be aware. The top 3 causes of injury mortality are traffic-related injuries, burns, and drowning. There are 7 specific effective strategies for reducing road traffic injuries: a minimum drinking age, appropriate child restraints and seatbelts, helmets for motorcycle and bicycle riders, reduced vehicle speeds around schools and residential areas, running lights on motorcycles, graduated licensing for drivers, and separation of different types of road users. There is insufficient evidence to demonstrate that school-based programs on drunk driving, increased pedestrian visibility, or designated driver programs are effective. Although these strategies have been proven effective, the data are based on research from the United States and may not be generalizable to other countries. It may be difficult to reduce vehicle speeds around schools when there is insufficient infrastructure for street signs. Alternatively, lack of separation of car and bus traffic from bicyclists and pedestrians contributes to unsafe and dangerous road conditions. This is more of a problem in lower- and middle-income countries, where bicycles and motorized 2-wheel vehicles are used to carry children as well as goods, while the drivers negotiate among rapidly moving vehicles. With rising income, these countries have seen increases in both the number of cars and the number of 2-wheeled vehicles, with a corresponding increase in the number of related injuries.

For reducing drowning deaths, strategies that have proven effective focus on creating barriers between children and water hazards, such as covering wells, buckets, and other standing sources of water, and placing high fences around pools (see Chapter 74). Burns have been addressed by advocating for installation of smoke detectors and lowering the temperature of water from water heaters (see Chapter 75). For the PEM practitioner, involvement in prevention depends largely on the local epidemiology of injuries and the factors contributing to those injuries. Involvement can include parental and patient education or activism to change local practices through laws and new community standards. Additionally, work can be done with groups of practitioners or healthcare centers to increase capacity to care for injured children. One can also work on a larger scale on projects initiated by a group such as the WHO, UNICEF, or Safe Kids Worldwide, to develop and evaluate intervention strategies that target specific preventable injuries.

Out-of-Hospital Care

Out-of-hospital care comprises access to emergency services,prehospital care, and interfacility transport of patients. Morbidity and mortality arise from delayed or limited access to emergency care, lack ofprehospital care, transport without proper monitoring or trained personnel, or delayed transport to a higher level of care. Safe transport of seriously ill children is a neglected global health issue. An emergency response system must address the following links in the patient's care: a communication system with prompt activation ofEMS, the correct assessment and initial treatment of the patient, and the rapid transport to definitive care.

Access to Care

When a child is injured or ill, a parent or caretaker must be able to access help and activate EMS. Many countries around the world have dedicated emergency numbers to rapidly dispatch medical, police, or fire services. The simple “112” emergency number has been adopted and is being phased in throughout the European Union member states, to be used to access medical, fire and police services in addition to secondary regional emergency access numbers. The universal U.S. emergency number system 911 today covers the large majority of the country (98%) and has enhanced features of automatically linking the phone number to an address. However, there remain limitations to universal access resulting from absence of phones in some households, unclear addresses in rural areas, and insufficient reach of the emergency system. In low- and middle-income countries, no such universal emergency numbers have been established, requiring access by direct dialing to an ambulance, if such private services exist. In most low- and middle-income countries, the family must bring the ill or injured child to the health facility for stabilization and treatment. For this to occur, families must overcome financial and geographic barriers, which can result in delayed presentation for care. This delay predictably increases the acuity of the illness or injury and associated complications, and decreases the likelihood of full recovery and survival.

Prehospital Care

In regions with maturing EMS systems, there must be adequately trained personnel to stabilize and transport the child to a medical facility. The quality and level of training of such prehospital personnel vary tremendously among countries and within regions of the same country. In urban areas, there is a greater concentration of medical care and therefore a greater opportunity to have strongprehospital training. In most of Asia and sub-Saharan Africa, trained personnel are used primarily to transfer patients between health facilities, and not from the initial site of illness or injury. In most high-income countries, EMS are dispatched to the patient.

A different approach to prehospital work is exemplified by the French EMS, called Service d'Aide Médicale Urgente (SAMU). In this system, a physician is integral to the prehospital team. A physician, typically an emergency medicine specialist in larger areas, will review every call for acuteness and can dispatch a physician-led team by ambulance to go to the patient’s home to assess, stabilize, and initiate treatment. This Franco-German system is used in other countries, including many in Latin America and Europe. There are no clear data on the cost-effectiveness and patient outcomes associated with delivery of patients to the nearest facility versus bringing hospital resources to the patient. Some research suggests, however, that it is difficult for ambulance-based physicians to maintain their field skills given the relatively low frequency of high-acuity or high-complexity cases.

Around the world, the effort to establish standardized approaches toprehospital care exists primarily in the form of courses to educate EMS and hospital personnel in the emergency management of patients. For trauma care, the WHO manuals Prehospital Trauma Care Systems and Guidelines for Essential Trauma Care both focus on guidelines for prehospital and trauma care systems that are affordable and sustainable. The AAP course Pediatric Education for Prehospital Professionals is a dynamic, modularized teaching tool designed to provide specific pediatrictprehospital education that can be adapted to any EMS system. Table 66-7 lists additionalprehospital resources.

Although most middle- and high-income countries have a system of trained EMS workers, low-income countries lack this advanced tier of emergency care. In these countries, commercial drivers, volunteers, and willing bystanders provide the first line of care. Training a cadre of first responders can rely on existing networks of aid or can be drawn from specific populations, such as students, soldiers, or public servants. Training needs to emphasize basic lifesaving and limb-saving interventions, including how to stop bleeding and support breathing, access advanced care, and splint broken limbs. In Ghana, for example, 335 taxi drivers participated in a first-aid course that relied heavily on demonstration and practice rather than knowledge transfer through didactic sessions. Taxi drivers were selected because they already provided much of the transport for injured patients, either voluntarily or for pay by the family. Two years after the course, external evaluators favorably rated the quality of their care in comparison with that of a group of untrained drivers. In rural areas, such first responders become vital in providing emergency interventions when more definitive care is distant. Thus, a system of trained first responders forms the foundation of an effectiveprehospital system.

Methods of Transport

In many low-income countries, there is no means of transport other than the family’s motorized or other type of transport. Health centers may only have 1 vehicle for transport to a higher-level facility. This

</tbody>
</table>
The emergency services in these centers are variable, but at least 1 pediatric-capable center, usually as part of an academic medical center. Anecdotally, most countries have developed at least 1 pediatric-specific emergency area (hydration and infusion rooms) can lessen the burden on inpatients. Children requiring emergency care frequently are not promptly recognized. Too often, children presenting to EDs are treated on a first-come first-served basis, in an approach that creates long waiting times for critically ill children, a contributor to unnecessary mortality. Medical facilities need to adopt an efficient and effective triage system in order to rapidly respond to the needs of patients and to assign the appropriate amount of resources. To this end, WHO has developed a course entitled Emergency Triage Assessment and Treatment (ETAT). This course teaches health practitioners to triage patients on arrival as having emergency, priority, or nonurgent signs and to provide emergency treatment for life-threatening conditions. ETAT emphasizes the evaluation of a patient’s ABCD status to identify emergency situations—the patency of the airway (A), the quality of breathing (B), the quality of circulation and presence of coma or convulsions (C), and the presence of severe dehydration (D).

One of the benefits of the ETAT guidelines is that they can be adapted to centers with limited resources and are applicable to areas with high morbidity and mortality from meningitis, dehydration, malaria, respiratory illness, and malnutrition. Another benefit is that the care algorithms are based on limited diagnostic studies, that is, hemoglobin measurement, blood smear for malaria, and bedside blood glucose testing. Widely accepted triage assessment guidelines are teachable to emergency care staff, and their adoption can provide better organization within a healthcare center. At the Queen Elizabeth Central Hospital in Blantyre, Malawi, for example, the institution of triage and rapid treatment in its emergency care center led to a 50% decrease in the mortality of children within 24 hr of presentation to the hospital, with a further 50% decrease as implementation and practice of triaging patients have continued.

Beyond triage, education on overall emergency center organization is a low-resource intervention that can obviate some of the obstacles to quality care delivery. Additionally, the arrangement of short-stay areas (hydration and infusion rooms) can lessen the burden on inpatient units.

Pediatric-Specific Emergency Centers
Descriptions on the development of pediatric-specific emergency centers are insufficient. Anecdotally, most countries have developed at least 1 pediatric-capable center, usually as part of an academic medical center. The emergency services in these centers are variable, but certainly can be a starting point from which to build overall improvement in pediatric emergency care.

Practitioners
Throughout the world, nurses, paramedics, and nonspecialist physicians provide most of the care to acutely ill or injured children. The majority of sick children attend local clinics or district or central hospitals, where financial and human resources are not always matched to the potential acuity of presenting patient complaints. Nominal supervision is provided to staff attending these patients. Pediatric EDs located in tertiary hospitals are often staffed by training physicians with little or no supervision from faculty, who themselves may have limited exposure to or training in PEM. General hospitals lack dedicated pediatric staff; guidelines as to which patients should be moved to a higher level of care are often not standardized and depend on local influences and/or cultural beliefs about health and illness.

Clinical Guidelines
The Integrated Management of Childhood Illnesses (IMCI) guidelines were developed by the WHO and UNICEF to provide assistance in the initial triage and management of the presenting signs and symptoms of the major killers of the under–5 yr population in first-level health facilities (e.g., clinics, health centers, and outpatient departments of hospitals). The flow charts within each chapter of the IMCI manuals allow easy accessibility to materials that can enhance education and outreach to less experienced health workers.

Evaluations in various countries of the implementation of IMCI guidelines have shown improvements in health worker performance and quality of care as well as decreases in delay in treatment and mortality of under–5 yr children. These guidelines also dramatically reduce the cost of healthcare. The WHO website provides all the necessary implementation tools, including course manuals and evaluation tools.

Trauma
Morbidity and mortality from trauma is one of the most prevalent problems for children worldwide. Trauma care presents the challenge of sequential, often simple, interventions that must be performed in a timely manner to limit the severity of the outcome. However, with lack of specific training, signs and symptoms of pediatric trauma may go unrecognized or may be underappreciated. Trauma courses such as Advanced Trauma Life Support are educational tools that can be disseminated to improve the quality of care at emergency centers worldwide. For low-resource settings, the WHO has developed the Integrated Management for Emergency and Essential Surgical Care toolkit, which provides clear directions and reasoning for the initial care of injured patients. Not expressly addressed in the Advanced Trauma Life Support course is specific concern about child abuse as the cause of trauma. This is an area of pediatric care that many countries do not yet address in their medical training, their law enforcement, or their judicial systems. The epidemiologic need for reliable trauma registries is great, as is the need to identify personnel with trauma management skill sets and dedicated trauma centers to serve as higher-level referral sites.

Equipment
Pediatric emergency textbooks, pediatric and emergency medicine professional organizations, WHO, and nongovernmental and governmental health organizations have all published pediatric emergency equipment guidelines, for a variety of settings in which acutely ill and injured children would present. Although these equipment guidelines may represent minimum supplies to treat the widest variety of pediatric emergencies, the roles of substitution and improvisation often provide for equivalent function of recommended supplies.

Inpatient Services
After the initial stabilization, children requiring ongoing care are admitted to the hospital. The quality of inpatient services varies greatly depending on institutional and provider experience, comfort with pediatric conditions, and the resources available to treat them. The WHO has produced the Pocket Book of Hospital Care for Children,
which is based on IMCI guidelines and focuses on inpatient management of high-morbidity/high-mortality illnesses common in developing countries.

**HUMANITARIAN DISASTERS**

Children are a vulnerable population who experience disproportionate suffering during humanitarian emergencies, either natural (earthquakes, tsunamis, hurricanes, floods, and droughts) or manmade (armed conflicts, terrorist attacks). The under–5 yr population is especially susceptible to infectious diseases, malnutrition, and trauma following disasters. The Rainbow Center for Global Child Health at the Case Western Reserve University School of Medicine offers a training course, Management of Humanitarian Emergencies: Focus on Children and Families, that concentrates on the needs of children in disasters. The intent of the Center is to educate and train health professionals, relief workers, and policymakers to recognize and address the unique needs of children affected by manmade and natural disasters worldwide. The AAP also maintains a CHILDisaster Network, which acts as an electronic database of child health professionals with education and experience in humanitarian emergencies. Nongovernmental organizations can access the database to solicit practitioners to aid in disaster response.

The WHO’s *Manual for the Health Care of Children in Humanitarian Emergencies* is based on IMCI guidelines and addresses the emergency care of children in disaster situations in which hospital facilities and resources are not immediately available. It goes beyond the IMCI guidelines by discussing initial assessment and management of trauma, burns, and poisonings. Preexisting IMCI guidelines assumed a functioning health system that facilitated the referral of children, which may not be available in all emergency situations. This manual also includes the initial management of severe conditions, such as injuries, burns, neonatal illness, and psychosocial problems, which are considered high priority in acute care settings.

**Exchange and Dissemination of Information**

The WHO established the HINARI (Health InterNetwork Access to Research Initiative) program to allow free or reduced-cost access to more than 6,200 journal publications. This Internet access is made available to the 108 countries with gross national income per capita less than $3,500. For middle-income countries not meeting the financial eligibility, Internet access continues to be a barrier, and resources may be limited to out-of-date textbooks and journals.

Another valuable tool is the website Pemdatabase.org. This nonproprietary site was started as an online resource for PEM practitioners. It contains links to PEM abstracts and articles, evidence-based reviews, pediatric resuscitation websites, relevant journals, as well as PEM conferences and professional organizations.

*Bibliography is available at Expert Consult.*
Chapter 66 ◆ Emergency Medical Services for Children 489.e1

Bibliography
Injuries are the leading cause of death in American children and young adults and are responsible for more childhood deaths than all other causes combined (see Chapter 5.1). Children are particularly vulnerable to injury for a number of reasons, including their small size, relative physical uncoordination, and limited ability to predict or understand danger. In addition, the immaturity of their developing bones, ligaments, and muscles; their thin body walls; and their relatively large heads, compared with total body surface area, make young children susceptible to serious or fatal injury from falls and collisions.

Most injuries in childhood are unintentional, and many are preventable. Motor vehicle–related injuries are the most common cause of unintentional injury and death for U.S. children, many of which are related to speeding, aggressive driving, failure to use proper passenger restraints, and/or alcohol. Consistent use of bicycle helmets could reduce the severity of head injuries, the leading cause of death when a bicyclist is struck by a car, by more than 80%. Four-sided fencing around swimming pools and use of flotation devices for every passenger in a boat could greatly reduce the risk of drowning, the second leading cause of accidental death in children younger than 5 yr and the third major cause of death in adolescents. Serious injuries can become fatal when appropriate medical care is delayed.

Rapid, effective bystander cardiopulmonary resuscitation (CPR) for children is associated with survival rates as high as 70%, with good neurologic outcome. However, bystander CPR is still provided for less than 50% of children who experience cardiac arrest outside medical settings. This has led to long-term survival rates of <40%, with many survivors suffering a poor neurologic outcome.

**APPROACH TO THE EMERGENCY EVALUATION OF A CHILD**

The first response to a pediatric emergency of any cause is a systematic, rapid general assessment of the scene and the child to identify immediate threats to the child, care providers, or others. If an emergency is identified, the emergency response system (emergency medical services [EMS]) should be activated immediately. Care providers should then proceed through primary, secondary, and tertiary assessments as allowed by the child's condition, safety of the scene, and resources available. This standardized approach provides organization to what might otherwise be a confusing or chaotic situation and reinforces an organized thought process for care providers. If, at any point in these assessments, the caregiver identifies a life-threatening problem, the assessment is halted and lifesaving interventions are begun. Further assessment and intervention should be delayed until other caregivers arrive or the condition is successfully treated.

**General Assessment**

Upon arrival at the scene of a compromised child, a caregiver's first task is a quick survey of the scene itself. Is the rescuer or child in imminent danger because of circumstances at the scene (fire, high-voltage electricity)? If so, can the child be safely extricated to a safe location for assessment and treatment? Can the child be safely moved with the appropriate precautions (i.e., cervical spine protection), if indicated? A rescuer is expected to proceed only if these safety conditions have been met.

Once the caregiver and patient's safety has been ensured, the caregiver performs a rapid visual survey of the child, assessing the child's general appearance and cardiopulmonary function. This action should be very quick (only a few seconds) and should include assessment of (1) general appearance (determining color, tone, alertness, and responsiveness); (2) adequacy of breathing (distinguishing between normal, comfortable respirations and respiratory distress or apnea); and (3) adequacy of circulation (identifying cyanosis, pallor, or mottling). A child found unresponsive from an unwitnessed collapse should be approached with a gentle touch and the verbal question, “Are you OK?” If there is no response, the caregiver should immediately shout for help and send someone to both activate the emergency response system (EMS) and locate an automated external defibrillator (AED) (Fig. 67-1). The provider should then determine whether the child is breathing and, if not, provide 2 rescue breaths as described later under “Recognition and Treatment of Respiratory Distress and Failure.” If the child is adequately breathing, then the circulation is quickly assessed. Any child with a heart rate below 60 beats/min or without a pulse requires immediate CPR, as described under...
"Recognition and Management of Cardiac Arrest." If the caregiver witnesses the sudden collapse of a child, the caregiver should have a higher suspicion for a sudden cardiac event. In this case, rapid deployment of an AED is of paramount importance. The provider should very briefly delay care of the child to activate EMS and locate the nearest AED.

Primary Assessment

Once the emergency response system has been activated and the child is determined not to need CPR, the caregiver should proceed with a primary assessment that includes a brief, hands-on assessment of cardiopulmonary and neurologic function and stability. This assessment includes a limited physical exam, evaluation of vital signs, and measurement of pulse oximetry if possible. Again, a standardized approach is best. The American Heart Association, in its Pediatric Advanced Life Support (PALS) curriculum, supports the structured format of **Airway, Breathing, Circulation, Disability, Exposure (ABCDE)**. The goal of the primary assessment is to obtain a focused, systems-based assessment of the child’s injuries or abnormalities, so that resuscitative efforts can be directed to these areas; if the caregiver identifies a life-threatening abnormality, further evaluation is postponed until appropriate corrective action has been taken.

The exam and vital sign data can be interpreted only if the caregiver has a thorough understanding of normal values. In pediatrics, normal respiratory rate, heart rate, and blood pressure have age-specific norms (Table 67-1). These ranges can be difficult to remember, especially if used infrequently. However, several standard principals apply: (1) no child’s respiratory rate should be >60 breaths/min for a sustained period; (2) normal heart rate is roughly 2-3 times normal respiratory rate for age; and (3) a simple guide for pediatric blood pressure is that...

*In sleep, infant heart rates may drop significantly lower, but if perfusion is maintained, no intervention is required.
†A blood pressure cuff should cover approximately two-thirds of the arm; too small a cuff yields spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings.
‡Many premature infants require mechanical ventilatory support, making their spontaneous respiratory rate less relevant.

Airway and Breathing

The most common precipitating event for cardiac instability in infants and children is respiratory insufficiency. Therefore, rapid assessment of respiratory failure and immediate restoration of adequate ventilation and oxygenation remain the first priority in the resuscitation of a child. Using a systematic approach, the caregiver should first assess whether the child’s airway is patent and maintainable. A healthy, patent airway is open and unobstructed, allowing normal respiration without noise or effort. A maintainable airway is one that is either already patent or can be made patent with a simple maneuver. To assess airway patency, the provider should look for breathing movements in the child’s chest and abdomen, listen for breath sounds, and feel the movement of air at the child’s mouth and nose. Abnormal breathing sounds (i.e., snoring or stridor), increased work of breathing, and apnea are all findings potentially consistent with airway obstruction. If there is evidence of airway obstruction, then maneuvers to relieve the obstruction should be instituted before the caregiver proceeds to evaluate the child’s breathing (see under “Recognition and Treatment of Respiratory Distress and Failure”).

Assessment of breathing includes evaluation of the child’s respiratory rate, respiratory effort, abnormal sounds, and pulse oximetry. Normal breathing appears comfortable, is quiet, and occurs at an appropriate rate. Abnormal respiratory rates include apnea and rates that are either too slow (bradypnea) or too fast (tachypnea). Bradypnea and irregular respiratory patterns require urgent attention, as they are often signs of impending respiratory failure and apnea. Signs of increased respiratory effort include nasal flaring, grunting, chest or neck muscle retractions, head bobbing, and “seesaw” respirations. Hemoglobin oxygen desaturation, as measured by pulse oximetry, often accompanies parenchymal lung disease apnea or airway obstruction. However, providers should keep in mind that adequate perfusion is required to produce a reliable oxygen saturation measurement. A child with low oxygen saturation is a child in distress. Central cyanosis is a sign of severe hypoxia and indicates an emergent need for oxygen supplementation and respiratory support.

Circulation

Cardiovascular function is assessed by evaluation of skin color and temperature, heart rate, heart rhythm, pulses, capillary refill time, and blood pressure. In nonhospital settings, much of the important information can be obtained without measuring the blood pressure; lack of blood pressure data should not prevent the provider for determining adequacy of circulation or implementing a lifesaving response. Mottling, pallor, delayed capillary refill, cyanosis, poor pulses, and cool extremities are all signs of diminished perfusion and compromised cardiac output. Tachycardia is the earliest and most reliable sign of shock, but it is itself fairly nonspecific and should be correlated with other components of the exam, such as weakness, threadiness, and absence of pulses. An age-specific approach to pulse assessment will yield best results.

Disability

In the setting of a pediatric emergency, disability refers to a child’s neurologic function in terms of the level of consciousness and cortical function. Standard evaluation of a child’s neurologic condition can be done quickly with an assessment of pupillary response to light (if one is available) and use of either of the standard scores used in pediatrics: the Alert, Verbal, Pain, Unresponsive (AVPU) Pediatric Response Scale and the Glasgow Coma Scale (GCS) (Tables 67-2, 67-3, and 68-1). The causes of decreased level of consciousness in children are numerous and include conditions as diverse as respiratory failure with hypoxia or hypercarbia, hypoglycemia, poisonings or drug overdose, trauma, seizures, infection, and shock. Most commonly, an ill or injured child has an altered level of consciousness because of respiratory compromise, circulatory compromise, or both. Any child with a depressed

level of consciousness should be immediately assessed for abnormaliti- 
ies in cardiorespiratory status.

**The Alert, Verbal, Pain, Unresponsive Pediatric Response Scale.** The AVPU scoring system is used to determine both a child’s level of consciousness and cerebral cortex function. Unlike the GCS (see later), the AVPU scale is not developmentally dependent—a child does not have to understand spoken language or follow commands, merely respond to a stimulus. The child is scored according to the amount of stimulus required to get a response, from alert (no stimulus, the child is already awake and interactive) to unresponsive (child does not respond to any stimulus) (see Table 67-2).

The Glasgow Coma Scale. Although the GCS has not been validated as a prognostic scoring system for infants and young children as it has been in adults, it is commonly used in the assessment of pediatric patients with an altered level of consciousness. The GCS is the most widely used method of evaluating a child’s neurologic function and has 3 components. Individual scores for eye opening, verbal response, and motor response are added together, with a maximum of 15 points (see Table 67-3). Patients with a GCS score ≤8 require aggres- sive management, including stabilization of the airway and breathing with endotracheal intubation and mechanical ventilation, respectively, and, if indicated, placement of an intracranial pressure monitoring device. The Full Outline of Unresponsiveness (FOUR) score is another useful assessment and monitoring tool (see Table 68-1).

**Exposure**

Exposure is the final component of the pediatric primary assessment. This component of the exam is reached only after the child’s airway, breathing, and circulation have been assessed and determined to be stable or have been stabilized through simple interventions. In this setting, exposure stands for the dual responsibility of the provider to both expose the child to assess for previously unidentified injuries and consider prolonged exposure in a cold environment as a possible cause of hypothermia and cardiopulmonary instability. The provider should undress the child (as is feasible and reasonable) to perform a focused physical exam, assessing for burns, bruising, bleeding, joint laxity, and fractures. If possible, the provider should assess the child’s temperature. All maneuvers should be performed with careful maintenance of cervical spine precautions.

**Secondary Assessment**

For care providers in community or outpatient settings, transfer of care of a child to emergency or hospital personnel may occur before a full secondary assessment is possible. However, before the child is removed from the scene and separated from witnesses or family, a brief history should be obtained for medical providers at the accepting facility. The components of a secondary assessment include a focused history and focused physical exam.

The history should be targeted to information that could explain cardiorespiratory or neurologic dysfunction and should take the form of a SAMPLE history (Signs/symptoms, Allergies, Medications, Past medical history, timing of Last meal, and Events leading to this situ- ation). Medical personnel not engaged in resuscitative efforts can be dispatched to elicit history from witnesses or relatives. The physical exam during the secondary assessment is a thorough head-to-toe exam, although the severity of the child’s illness or injury could necessitate curtailing portions of the exam or postponing nonessential elements until a later time.

**Tertiary Assessment**

The tertiary assessment occurs in a hospital setting, where ancillary laboratory and radiographic assessments contribute to a thorough understanding of the child’s condition. A basic blood chemistry profile, complete blood count, liver function tests, coagulation studies, and arterial blood gas analyses give fairly broad (but somewhat nonspec- ific) estimates of renal function, acid–base balance, cardiorespiratory function, and presence or absence of shock. Chest radiographs can be useful to evaluate both the heart and lungs, although more detailed estimates of heart function and cardiac output can be made with echocardiography. Arterial and central venous catheters can be placed to monitor arterial and central venous pressure (see under “Vascular Access”).

**RECOGNITION AND TREATMENT OF RESPIRATORY DISTRESS AND FAILURE**

The goals of initial management of respiratory distress or failure are to rapidly stabilize the child’s airway and breathing and to identify the cause of the problem so that further therapeutic efforts can be appro- priately directed.

**Airway Obstruction**

Children <5 yr old are particularly susceptible to foreign-body aspira- tion and choking. Liquids are the most common cause of choking in infants, whereas small objects and food (e.g., grapes, nuts, hot dogs, candies) are the most common source of foreign bodies in the airways of toddlers and older children. A history consistent with foreign-body aspiration is considered diagnostic. Any child in the proper setting with the sudden onset of choking, stridor, or wheezing has foreign-body aspiration until proven otherwise.

Airway obstruction is treated with a sequential approach, starting with the head-tilt/chin-lift maneuver to open and support the airway, followed by inspection for a foreign body, and, if possible and reasonable, suctioning or if one is visualized (Fig. 67-2). Blind suctioning or finger sweeps of the mouth are not recommended. A nasopharyngeal airway or oropharyngeal airway can be inserted for airway support, if indi- cated. A conscious child suspected of having a partial foreign-body obstruction should be permitted to cough spontaneously until coughing is no longer effective, respiratory distress and stridor increase, or the child becomes unconscious.

If the child becomes unconscious, the child should be gently placed on the ground, supine. The provider should then open the airway with the head-tilt/chin-lift maneuver and attempt mouth-to-mouth ventilation (Figs. 67-3 and 67-4). If ventilation is unsuccessful, the airway is repositioned, and ventilation attempted again. If there is still no chest rise, attempts to remove a foreign body are indicated. In an infant <1 yr old, a combination of 5 back blows and 5 chest thrusts is administered.

**Figure 67-2** Opening the airway with the head-tilt/chin-lift maneuver. One hand is used to tilt the head, extending the neck. The index finger of the rescuer’s other hand lifts the mandible outward by lifting the chin. Head-tilt should not be performed if a cervical spine injury is suspected. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Sub- committees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)
Chapter 67  Pediatric Emergencies and Resuscitation

(Fig. 67-5). After each cycle of back blows and chest thrusts, the child’s mouth should be visually inspected for the presence of the foreign body. If identified within finger’s reach, it should be removed with a gentle finger sweep. If no foreign body is visual, ventilation is again attempted. If this is unsuccessful, the head is repositioned, and ventilation attempted again. If there is no chest rise, the series of back blows and chest thrusts is repeated.

For a conscious child >1 yr old, providers should give a series of 5 abdominal thrusts (Heimlich maneuver) with the child standing or sitting (Fig. 67-6); this should occur with the child lying down if unconscious (Fig. 67-7). After the abdominal thrusts, the airway is examined for a foreign body, which should be removed if visualized. If no foreign body is seen, the head is repositioned, and ventilation attempted. If it is unsuccessful, the head is repositioned and ventilation is attempted again. If these efforts are unsuccessful, the Heimlich sequence is repeated.

(Fig. 67-6) Abdominal thrusts with the victim standing or sitting (conscious). (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)

(Fig. 67-5) Back blows (top) and chest thrusts (bottom) to relieve foreign-body airway obstruction in the infant. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)
Airway Narrowing

Airway obstruction can also be caused by airway narrowing, in both the upper and lower airways. Upper airway obstruction refers to narrowing of the extrathoracic portion of the airway, including the oropharynx, larynx, and trachea. In the upper airways, narrowing is most often caused by airway edema (croup or anaphylaxis). Lower airway disease affects all intrathoracic airways, notably the bronchi and bronchioles. In the lower airways, bronchiolitis and acute asthma exacerbations are the major contributors to intrathoracic airway obstruction in children, causing airway narrowing through a combination of airway swelling, mucus production, and circumferential smooth muscle constriction of smaller airways.

Airway support for these processes is dictated by both the underlying condition and the clinical severity of the problem. In cases of mild upper airway obstruction, the child has minimally elevated work of breathing (evidenced by tachypnea and few to mild retractions). Stridor, if present at all, should be audible with only coughing or activity. Children with these findings can be supported with nebulized cool mist and supplemental oxygen as needed. In cases with moderate obstruction, in which the child has a higher work of breathing and more pronounced stridor, nebulized racemic epinephrine and oral or intravenous (IV) dexamethasone can be added. Children with severe upper airway obstruction have marked retractions, prominent stridor, and decreased air entry on auscultation of the lung fields. Most children with significant airway obstruction are also hypoxic, and many appear dyspneic and agitated. A child in severe distress needs to be closely observed, as the signs of impending respiratory failure may be initially confused with improvement. Stridor becomes quieter and retractions less prominent when a child’s respiratory effort begins to diminish. The child in respiratory failure can be distinguished from one who is improving by evidence of poor air movement on auscultation and lethargy or decreased level of consciousness from hypercarbia, hypoxia, or both. When anaphylaxis is suspected as the cause for upper airway edema, providers should administer an intramuscular or IV dose of epinephrine as needed (see Chapter 149). No matter the cause, any child in impending respiratory failure should be prepared for endotracheal intubation and respiratory support.

In cases of lower airway obstruction, therapies are targeted to both relieving the obstruction and reducing the child’s work of breathing. Inhaled bronchodilators, such as albuterol, augmented by oral or IV corticosteroids, remain the mainstay of therapy in settings of mild to moderate acute distress caused by lower airway obstruction. Children with more significant obstruction appear dyspneic, with tachypnea, retractions, and easily audible wheezing. In these cases, the addition of an anticholinergic agent, such as nebulized ipratropium bromide, or a smooth muscle relaxant, such as magnesium sulfate, may provide further relief, although the evidence for these measures remains controversial (see Chapter 144). Supplemental oxygen and IV fluid hydration can also be useful adjuncts. As in cases of upper airway obstruction, impending respiratory failure in children with lower airway obstruction can be insidious. When diagnosed early in a school-age child who is cooperative, respiratory failure can be averted through judicious use of noninvasive support, with continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or heliox (combined helium-oxygen therapy). Endotracheal intubation should be performed only by skilled providers, preferably in a hospital setting, because there is a high risk of respiratory and circulatory compromise in patients with lower airway obstruction during the procedure.

Parenchymal Lung Disease

Parenchymal lung disease includes a heterogeneous list of conditions, such as pneumonia, acute respiratory distress syndrome, pneumonitis, bronchiolitis, bronchopulmonary dysplasia, cystic fibrosis, and pulmonary edema. The commonalities of these conditions are their effects on the small airways and alveoli, including inflammation and exudation leading to consolidation of lung tissue, decreased gas exchange, and increased work of breathing. Clinical management of these conditions includes specific treatment as indicated (i.e., antibiotics for bacterial pneumonia) and supportive care in the form of supplemental oxygen, noninvasive respiratory support (with CPAP or BiPAP), or invasive mechanical ventilation.

Advanced Airway Management Techniques

Bag-Valve-Mask Positive Pressure Ventilation

Rescue breathing with a bag-valve-mask apparatus can be as effective as endotracheal intubation and safer when the provider is inexperienced with intubation. Bag-valve-mask ventilation itself requires training to ensure that the provider is competent to select the correct mask size, open the child’s airway, form a tight seal between the mask and the child’s face, deliver effective ventilation, and assess the effectiveness of the ventilation. An appropriately sized mask is one that fits over the child’s mouth and nose but does not extend below the chin or over the eyes (Fig. 67-8). An adequate seal is best achieved via a combination “C–E” grip on the mask, in which the thumb and index finger form the letter “C” on top of the mask, pressing the mask downward onto the child’s face, and the remaining 3 fingers form an “E” grip under the child’s mandible, holding the jaw forward and extending the head up toward the mask. Using this method, the care provider can secure the mask to the child’s face with 1 hand and use the other hand to compress the ventilation bag (Fig. 67-9).

The provider may have to move the head and neck through a range of positions to find the one that best maintains airway patency and allows maximal ventilation. In infants and young children, optimal ventilation is often provided when the child’s head is in the neutral “sniffing” position without hyperextension of the head (Fig. 67-10). Poor chest rise and persistently low oxygen saturation values indicate inadequate ventilation. In this setting, the care provider should recheck the mask’s seal on the child’s face, reposition the child’s head, and consider suctioning the airway if indicated. If these maneuvers do not restore ventilation, then the provider should consider endotracheal intubation.

Endotracheal Intubation

A child requires intubation when at least 1 of these conditions exists: (1) the child is unable to maintain airway patency or protect the airway against aspiration (as occurs in settings of neurologic compromise); (2) the child is failing to maintain adequate oxygenation; (3) the child is failing to control blood carbon dioxide levels and maintain safe
situation is an emergency (i.e., apnea, asystole, unresponsiveness) and the administration of drugs would cause an unacceptable delay. Because many intubations in critically ill children are emergency procedures, caregivers should be prepared for rapid sequence intubation (RSI) (Fig. 67-11; Table 67-4). The goals of RSI are to induce anesthesia and paralysis and to complete intubation quickly. This approach minimizes elevations of intracranial pressure and blood pressure that may accompany intubation in awake or lightly sedated patients. Because the stomach generally cannot be emptied before RSI, the Sellick maneuver (downward pressure on the cricoid cartilage to compress the esophagus against the vertebral column) should be used to prevent aspiration of gastric contents.

Once the patient is intubated, proper ET placement should be assessed by auscultation of breath sounds, evidence of symmetric chest rise, and analysis of exhaled carbon dioxide (CO2) by a colorimetric device placed within the respiratory tubing near the ET or a device that directly measures carbon dioxide elimination (i.e., capnogram or capnograph). Chest radiography is necessary to confirm appropriate tube position.

**RECOGNITION AND MANAGEMENT OF SHOCK**

In simple terms, shock occurs when oxygen and nutrient delivery to the tissues is inadequate to meet metabolic demands (see Chapter 70).
flow to the body, as occurs when a ductus arteriosus closes in a child with ductus-dependent systemic blood flow in pericardial tamponade, tension pneumothorax, or massive pulmonary embolism.

The evaluation of a child in shock should proceed as described in the preceding sections on primary, secondary, and tertiary assessments. If the child presents in a hospital setting, providers should obtain central venous and arterial access to permit a more thorough laboratory assessment of all organ systems, including studies of renal and liver function, acid–base balance and presence of lactic acidosis, hypoxemia and/or hypercapnia, and evidence of coagulopathy or disseminated intravascular coagulation. Chest radiography and more sophisticated assessments, such as echocardiography, may also be useful. Respiratory and cardiovascular support should be provided as indicated.

The treatment of shock focuses on the modifiable determinants of oxygen delivery while reducing the imbalance between oxygen demand and supply. A multipronged approach is recommended; it consists of optimizing the oxygen content of the blood, improving the volume and distribution of cardiac output, correcting metabolic derangements, and reducing oxygen demand. Blood oxygen content is maximized when hemoglobin values are normal and 100% of available hemoglobin is saturated with oxygen. Transfusion should be considered in the presence of hemorrhagic or distributive shock, in which crystalloid volume resuscitation has led to hemodilution and anemia. High oxygen saturations may be achieved by simple maneuvers such as oxygen administration via nasal cannula or face mask, but supportive measures that provide positive pressure, such as CPAP, BiPAP, or even mechanical ventilation, may be necessary. Therapies to increase cardiac output should be selected on the basis of underlying pathophysiology. For hypovolemic and distributive shock, aggressive volume resuscitation, guided by arterial and central venous pressures, is the mainstay of therapy. In obstructive shock, relief of the obstruction is critical. The ductus arteriosus can often be reopened with prostaglandin administration, and tamponade physiology can be relieved with appropriate drain placement, as described under “Nonvascular Emergency Procedures.”

**RECOGNITION OF BRADYARRHYTHMIAS AND TACHYARRHYTHMIAS**

In the advanced life support setting, arrhythmias are most usefully classified according to the observed heart rate (slow or fast) and its effect on perfusion (adequate or poor). If, in the primary survey, a caregiver finds a child with an abnormal heart rate plus poor perfusion and/or altered mental status, then the rhythm is inadequate no matter its rate. In those settings, the child is diagnosed with shock, and further evaluation is halted until appropriate resuscitation has been initiated.

**Bradyarrhythmias**

By definition, a child is bradycardic when the heart rate is slower than the normal range for age (see Table 67-1). Sinus bradycardia can be a harmless incidental finding in an otherwise healthy person and is not commonly associated with cardiac compromise. A relative bradycardia occurs when the heart rate is too slow for a child’s activity level or metabolic needs. A clinically significant bradycardia occurs when the heart rate is slow and there are signs of systemic hypoperfusion (i.e., pallor, altered mental status, hypotension, acidosis). Symptomatic bradycardia occurs most often in the setting of hypoxia but can also be caused by hypoglycemia, hypocalcemia, other electrolyte abnormalities, and intracranial hypertension. Bradyarrhythmias are often the most common prearrest rhythms in young children.

Initial management of symptomatic bradycardia includes support or opening of the airway and confirming or establishing adequate oxygenation and ventilation (Fig. 67-12). After the child’s breathing has been secured, the child should be reassessed for continued bradycardia and poor perfusion. If cardiac compromise was solely the result of respiratory insufficiency, support of the child’s airway and breathing may have been sufficient to restore normal hemodynamics. If respiratory support does not correct the perfusion abnormalities, then further care is based on the quality of perfusion and the degree of

The definition of shock does not include hypotension, and it is important for care providers to understand that shock does not begin when blood pressure drops; it merely worsens and becomes more difficult to treat once blood pressure is abnormal.

Early compensated shock, whereby oxygen delivery is mostly preserved through compensatory mechanisms, is defined by the presence of normal blood pressure. When compensatory mechanisms fail, the shock progresses to decompensated shock, which is defined by hypotension and organ dysfunction. In irreversible shock, organ failure progresses and death ensues.

Shock is also often described according to the underlying pathophysiology, which dictates the appropriate therapeutic response. Hypovolemic shock is the most common type of shock in children worldwide, usually related to fluid losses from severe diarrhea. Hemorrhage is a cause of hypovolemic shock after trauma or intestinal hemorrhage. When hypovolemia occurs as a result of third spacing of intravascular fluids into the extravascular compartment, the shock is described as distributive shock. The most common causes of distributive shock are sepsis and burn injuries, in which release of inflammatory cytokines causes massive capillary leak of fluid and proteins, leading to low oncotic pressure and intravascular volume. In settings of profound myocardial dysfunction, a child has tissue hypoperfusion from cardiacogenic shock. The most common causes of cardiogenic shock are congenital heart disease, myocarditis, and cardiomyopathies. Obstructive shock occurs when cardiac output is lowered by obstruction of blood
bradycardia. A heart rate less than 60 beats/min with poor perfusion is an indication to begin chest compressions. If the bradycardia persists, vascular access should be obtained; resuscitative epinephrine should be administered, and it should be repeated every 3-5 min for persistent symptomatic bradycardia. If increased vagal tone (e.g., in the setting of head injury with raised intracranial pressure) or primary atrioventricular block is suspected, atropine can also be given. For cases of refractory bradycardia, cardiac pacing should be considered. During the resuscitation of a child with bradycardia, providers should assess and treat factors known to cause bradycardia, referred to collectively as the 6 Hs (hypoxia, hypovolemia, hydrogen ions [acidosis], hypokalemia or hyperkalemia, hypoglycemia, hypothermia), and 5 Ts (toxins, tamponade, tension pneumothorax, thrombosis [in either the pulmonary or cardiac circulations], and trauma [causing hypovolemia, intracranial hypertension, cardiac compromise or tamponade]) (Table 67-5).

Tachyarrhythmias
Tachyarrhythmias represent a variety of rhythm disturbances of both atrial and ventricular origin (see Chapter 435). Sinus tachycardia is a normal physiologic response to the body’s need for increased cardiac output or oxygen delivery, as occurs with fever, exercise, or stress. It can also occur in more pathologic states, such as hypovolemia, anemia, pain, anxiety, and metabolic stress. Tachyarrhythmias that do not originate in the sinus node are often categorized as narrow complex rhythms (those originating in the atrium, such as atrial flutter or supraventricular tachycardia [SVT]) and wide complex rhythms (those rhythms of ventricular origin, such as ventricular tachycardia).

The initial management of tachycardia includes confirmation that the child has an adequate airway and life-sustaining breathing and circulation (Fig. 67-13). For children with persistent symptoms, further treatment is based on whether the QRS complex of the electrocardiogram (ECG) is narrow (≤0.09 sec) or wide (>0.09 sec). For narrow complex tachycardia, providers must distinguish between sinus tachycardia and SVT. In sinus tachycardia, (a) the history and onset are consistent with a known cause of tachycardia, such as fever or dehydration and (b) P waves are consistently present, are of normal morphology, and occur at a rate that varies somewhat. In SVT, (a) onset is often abrupt without prodrome and (b) P waves are absent or polymorphic, and when present, their rate is often fairly steady at or above 220 beats/min. For children with SVT and good perfusion, vagal maneuvers can be attempted. In cases in which SVT is associated with poor perfusion, providers should rapidly move to convert the child’s heart rhythm back to sinus rhythm. If the child already has IV access, then adenosine can be given via IV with rapid “push.” Adenosine has an extremely short half-life, so a proximal IV is best, and the adenosine should be set up with a 3-way stopcock so it can be given and immediately flushed into the circulation. If the child does not have IV access, adenosine does

not successfully convert the heart rhythm back to sinus rhythm, then synchronized cardioversion, using 0.5-1.0 joule/kg, should be performed. In cases of wide complex tachycardia, providers should move immediately to cardioversion and increase the dose to 2 joules/kg if 1 joule/kg is not effective. As with cases of bradycardia, providers should review the 6 Hs and 5 Ts to identify factors that might be contributing to the tachycardia (see Table 67-5).

RECOGNITION AND MANAGEMENT OF CARDIAC ARREST

Cardiac arrest occurs when the heart fails as an effective pump and blood flow ceases. Outwardly, the patient in cardiac arrest presents as unresponsive and apneic with no palpable pulse. Internally, the cessation of nutrient flow causes progressive tissue ischemia and organ dysfunction. If not rapidly reversed, cardiac arrest leads to progressive deterioration in brain and heart function such that resuscitation and recovery are no longer possible.

Pediatric cardiac arrest is rarely caused by a sudden coronary event or arrhythmia. Instead, cardiac arrest in children is most often the end result of progressive asphyxia, caused by tissue hypoxia, acidosis, and nutrient depletion at the end stages of respiratory deterioration, shock, or heart failure. Therefore, the most important treatment of cardiac arrest is anticipation and preventive: Intervening when a child manifests respiratory distress or early stages of shock can prevent deterioration to full-blown arrest. When sudden cardiac arrest does occur, it is most often associated with an arrhythmia, specifically ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). In sudden events such as these, the key to successful resuscitation is early

*Adult dose. Adjust for size of child. See Table 67-6.

Cardiac arrest is recognized from general and primary survey findings consistent with a pale or cyanotic child who is unresponsive, apneic, and pulseless. Even experienced providers have a relatively high error rate when asked to determine presence or absence of pulse in a child. Therefore, any child found unresponsive and apneic can be presumed to be in cardiac arrest, and a rescuer should respond accordingly.

A lone rescuer for an unwitnessed pediatric cardiac arrest in an outpatient setting should treat the arrest as asphyxial in nature and should immediately initiate CPR. The rescuer should perform recognition of the arrhythmia and prompt treatment with high-quality CPR and defibrillation.

The principle behind high-quality CPR is that adequate chest compressions—those that circulate blood around the body with a good pulse pressure—are the most important component of CPR. The caregiver providing chest compressions should push hard, push fast, allow for complete chest recoil, and minimize interruptions. Ideally, chest compressions should be interrupted only for ventilation, a rhythm check, or delivery of a defibrillating shock.
initial rescue breaths and 2 min of chest compressions and ventilations before leaving the child to activate the emergency response system. For an in-hospital arrest, the provider should call for help and send someone else to activate the emergency response system while beginning CPR. A lone rescuer in an outpatient setting who witnesses a child’s sudden collapse should treat the arrest as a primary arrhythmia, should immediately activate the EMS system, and should obtain an AED. Upon returning to the child, the rescuer should confirm pulselessness, turn on the AED, place the leads on the child’s chest, and follow the defibrillator’s voice commands.

The initial step in CPR for a child of any age is to restore ventilation and oxygenation as quickly as possible. Upon confirmation of unresponsiveness, apnea, and pulselessness, the provider should open the airway with a head-tilt/chin-lift maneuver (or jaw-thrust if cervical spine trauma is suspected) and provide 2 initial rescue breaths (Fig. 67-14). These breaths are deep and slow, lasting approximately 1 sec per breath. The breaths are adequate if they cause the chest to rise and fall and improve the child’s color. If the breaths appear inadequate, the child should be repositioned, and the breaths delivered again. If the breaths remain ineffective, the provider should assess the child for foreign body aspiration. After 2 effective rescue breaths, the child’s pulse should be assessed. If the child has a pulse but remains apneic (or with ineffective breathing), then the rescuer should continue to provide assisted ventilation at an age-appropriate rate. Infants and children ≤ 1 y r old should receive rescue breathing at a rate of roughly 15-20 breaths/min, or roughly 1 breath every 3-5 sec. Children > 1 y r old should receive 10-12 breaths/min, or 1 breath every 5-6 sec.

If the child remains pulseless, chest compressions should be initiated. Chest compressions in infants < 1 yr old may be performed by placing 2 thumbs on the midsternum with the hands encircling the thorax or by placing 2 fingers over the midsternum and compressing (Figs. 67-15 and 67-16). For children > 1 yr old, the care provider should perform chest compressions over the lower half of the sternum with the heel of 1 hand, or with 2 hands as used for adult resuscitation (Fig. 67-17). In all cases, care should be taken to avoid compression of the xiphoid and the ribs. When feasible, a cardiac resuscitation board (Fig. 67-18). In all cases, care should be taken to avoid compression of the xiphoid and the ribs. When feasible, a cardiac resuscitation board

Figure 67-14 Combined jaw-thrust/spine stabilization maneuver for the pediatric trauma victim. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, JAMA 268:2251–2261, 1992.)

at a level that is compatible with survival. If resuscitative efforts do not succeed in reestablishing life-sustaining breathing and circulation, the medical team must decide whether continued efforts are warranted or whether the resuscitation should be stopped. If EMS care is en route, bringing the potential for further escalation in care such as endotracheal intubation, vascular access, and medications, CPR should be continued as long as possible or deemed reasonable by the rescuers.

In the in-hospital setting, the ECG should dictate further resuscitative efforts. For children without a pulse and in asystole or electromechanical dissociation (pulseless electrical activity), providers should continue rescue breathing and CPR, obtain vascular access, and give emergency IV epinephrine (Fig. 67-18). For continued asystole or pulseless electrical activity, epinephrine can be repeated every 3-5 min. Patient history, physical exam findings, and laboratory evaluation should be used to elicit correctable causes of arrest (such as the 6 Hs and 5 Ts) (see Table 67-5). CPR should be continued after epinephrine administration, to circulate the drug through the body. After 5 cycles of CPR, providers should reassess the child for the presence of a pulse or a change in the ECG rhythm that would necessitate a different response.

For those children with pulseless VT or VF, emergency defibrillation is indicated (see Fig. 67-18). Providers should apply the pads to the child’s bare chest and back and follow the verbal instructions given by the AED. For younger children, a defibrillator (if available) set to the dose of 2 joules/kg should be used. Ideally, the AED used in a child
Traditionally, continuing CPR >20 min in children with in-hospital cardiac arrest has been considered futile. With current practice for CPR, survival for in-hospital cardiac arrest is approximately 40% for CPR duration <15 min compared with approximately 12% for CPR lasting >35 min. Survivors had a favorable neurologic outcome in 70% with a CPR duration <15 min compared with 60% for those requiring resuscitation for >35 min.

VASCULAR ACCESS

Venous Access
Veins suitable for cannulation are numerous, but there is considerable anatomic variation from patient to patient. In the upper extremities, the median antecubital vein, located in the antecubital fossa, is often the largest and easiest to access (Fig. 67-19). Many veins on the dorsum of the hand are also suitable for cannulation because they are often large and easily located on the flat surface of the dorsum of the hand, and their cannulation is well tolerated. The cephalic vein is usually cannulated at the wrist, along the forearm, or at the elbow. The median vein of the forearm is also suitable because it lies along a flat surface of the forearm. In the lower extremity, the great saphenous vein, located just anterior to the medial malleolus, is accessible in most patients. The dorsum of the foot usually has a large vein in the midline, passing across the ankle joint, but catheters are difficult to maintain in this vein because dorsiflexion tends to dislodge them. A second large vein on the lateral side of the foot, running in the horizontal plane, usually 1-2 cm dorsal to the lower margin of the foot, is preferable (Fig. 67-20). The most notable scalp veins are the superficial temporal (just anterior to the ear) and posterior auricular (just behind the ear).

Deeper and larger central veins can provide more reliable, large-bore access for medications, nutritive solutions, and blood sampling than peripheral venous lines. They may be reached by percutaneous cannulation or surgical exposure. In infants and young children, the femoral vein is often the easiest to access and cannulate, but the internal jugular and subclavian veins may also be used (Figs. 67-21 and 67-22). Because of its proximity to the median nerve, the brachial vein is not often recommended for cannulation.

Intraosseous Access
Intraosseous (IO) needles (for intramedullary venous plexus access) are special rigid, large-bore needles that resemble those used for bone marrow aspiration. IO cannulation is recommended for patients for whom IV access proves difficult or unattainable, even in older children. If venous access is not available within 1 min in a child with cardio-pulmonary arrest, an IO needle should be placed in the anterior proximal tibia (with care taken to avoid traversing the epiphyseal plate). The needle should penetrate the anterior layer of compact bone, and its tip

≤8 yr of age should be equipped with an attenuated adult dose or should be designed for children; if neither device is available, a standard adult AED should be used. CPR should be immediately restarted after defibrillation. Emergency dose epinephrine can also be administered with another 5 cycles of CPR to ensure its circulation throughout the child’s body. If the ECG rhythm continues to show VF or VT, defibrillation can be alternated with epinephrine. For refractory VF or VT, an IV antiarrhythmic, such as amiodarone or lidocaine, can be given (Tables 67-6 and 67-7).

New approaches to CPR in adults have highlighted the potential value of bystander chest compression alone in the initial resuscitation in a community setting. In addition, the combination of vasopressin, methylprednisolone, and epinephrine during an in-hospital cardiac arrest followed by hydrocortisone during the postresuscitation shock period has resulted in a better outcome than patients treated with epinephrine alone. Whether these observations are applicable to young children, who often have different etiologies for cardiopulmonary arrest, has not been determined.

advanced into the spongy interior of the bone (Fig. 67-23). Commercially available IO kits frequently include drills that obviate the complications of needle placement associated with manual placement. Any and all medications, blood products, and fluids may be administered through the IO route, including all medications required for emergency resuscitation. Complications are uncommon, but may include osteomyelitis with prolonged infusions and tibial fracture.

### Arterial Access

Arterial access is indicated when care providers need frequent blood sampling, particularly to assess adequacy of oxygenation, ventilation, or acid–base balance, and/or continuous blood pressure monitoring. The radial artery, the most commonly cannulated artery, lies on the lateral side of the anterior wrist, just medial to the styloid process of the radius (Fig. 67-24). The ulnar artery, just lateral to the tendon of the flexor carpi ulnaris, is used less often because of its proximity to the ulnar nerve. Useful sites in the lower extremity, particularly in neonates and infants, are the dorsalis pedis artery, on the dorsum of the foot between the tendons of the tibialis anterior and the extensor hallucis longus, and the posterior tibial artery, posterior to the medial...
Thoracentesis and Chest Tube Placement

Thoracentesis is the placement of a needle or catheter into the pleural space to evacuate fluid, blood, or air. Most insertions are performed in one of the intercostal spaces between the 4th and 9th ribs in the plane of the midaxillary line. After appropriate systemic and local anesthesia/sedation is performed as clinically indicated, a skin incision is made, and dissection through the chest wall is accomplished in layers with use of blunt dissection techniques. The needle (and later, the chest tube) that enters the pleural space should penetrate the intercostal space by passing over the superior edge of the lower rib, because there are larger vessels along the inferior edge of the rib. Ideally, the chest tube should lie anterior in the pleural space for air accumulation, and posterior for fluid accumulation. A radiograph must be obtained to verify chest tube placement and evacuation of the pleural space.

Pericardiocentesis

When fluid, blood, or gas accumulates in the pericardial sac, a danger is that the heart will be compressed and will not be able to fill and empty with normal volumes of blood, leading to diminished cardiac output. The cardinal signs of such a restrictive pericardial effusion are tachycardia, hypotension, and decreasing oxygen saturation. Pericardiocentesis includes needle aspiration of the pericardial sac, often followed by the placement of a catheter for continuous drainage. As for thoracentesis, chest radiography should be done to confirm catheter location as well as to evaluate for presence of any complications, such as pneumothorax or hemothorax.

POSTRESUSCITATION CARE

After successful resuscitation, close observation in an intensive care unit, where the child can receive ongoing mult орган system assessments and support, is critical. Optimal postresuscitation care includes ongoing support of cardiovascular and respiratory system function as needed and the identification and treatment of other organ system dysfunction that may have contributed to (or resulted from) the child’s cardiopulmonary instability. Good postresuscitation intensive care also includes supportive services for the child’s parents, siblings, family, and friends.

Induced hypothermia (32-34°C [89.6-91.4°F] for \( \approx 48 \) hr) may improve survival and neurologic function in adult and pediatric survivors of CPR. This is a controversial treatment that has inconsistently proven beneficial in comatose adult survivors of cardiac arrest. Randomized clinical trials in children are in progress. Furthermore, hypothermia must be avoided. Hypoxic-ischemic encephalopathy with subsequent development of seizures, intellectual impairment, and spasticity, is a serious and common complication of cardiac arrest. In addition hyperglycemia and hypoglycemia should be avoided.

Postresuscitation management generally has 2 phases, similar to earlier, emergency resuscitative care. First, the providers must assess the child’s airway and breathing and must support oxygenation and ventilation as indicated. If the child has ongoing respiratory failure and has been supported with bag-valve-mask ventilation until this time, the providers should now move forward with intubation. Once the child is intubated, mechanical ventilation must be established, and respiratory assessments performed, such as chest radiography and arterial blood gas sampling and analysis. The child’s circulatory system must also be assessed and supported as needed. Continuous arterial blood pressure monitoring can help the provider determine the need for, and response to, inotropic and chronotropic medications (see Table 67-7). Once the ABCs have been managed, providers can move on to full organ system assessments. A systematic approach that employs a full physical exam and laboratory evaluation to reveal the child’s respiratory, cardiovascular, neurologic, gastrointestinal, renal, and hematologic system function should be used.

Communication with the family is an essential element of postresuscitation care. The family should be thoroughly briefed on the elements of the resuscitation performed, the child’s condition, and ongoing medical concerns, uncertainties, or issues by the most senior provider available. This provider should be available to answer the family’s questions, clarify information, and provide comfort. Other support staff, such as social workers and chaplains, should be contacted, as the family wishes, to provide additional support and comfort. For situations in which the resuscitation is ongoing and the child is not expected to survive, the American Academy of Pediatrics recommends that the provider make every effort possible to have the family present at the bedside if they wish. Family presence during CPR or other emergency resuscitative efforts, even if the child dies, is associated with a more positive medical experience than if they are excluded. In cases in which the child is critically ill but stable, the family should be brought to the bedside as soon as the healthcare team deems it safe and appropriate.

NEUROCRITICAL CARE PRINCIPLES

The brain has high metabolic demands, which are further increased during growth and development. Preservation of nutrient supply to the brain is the mainstay of care for children with evolving brain injuries. Intracranial dynamics describes the physics of the interactions of the contents—brain parenchyma, blood (arterial, venous, capillary) and cerebrospinal fluid (CSF)—within the cranium. Normally, brain parenchyma accounts for up to 85% of the contents of the cranial vault, and the remaining portion is divided between CSF and blood. The brain resides in a relatively rigid cranial vault, and cranial compliance decreases with age as the skull ossification centers gradually replace cartilage with bone. The intracranial pressure (ICP) is derived from the volume of its components and the bony compliance. The perfusion pressure of the brain (cerebral perfusion pressure [CPP]) is equal to the pressure of blood entering the cranium (mean arterial pressure) minus the ICP, in most cases.

Increases in intracranial volume can result from swelling, masses, or increases in blood and CSF volumes. As these volumes increase, compensatory mechanisms decrease ICP by (a) decreasing CSF volume (CSF is displaced into the spinal canal or absorbed by arachnoid villi), (b) decreasing cerebral blood volume (venous blood return to the thorax is augmented), and/or (c) increasing cranial volume (sutures pathologically expand or bone is remodeled). Once compensatory mechanisms are exhausted (the increase in cranial volume is too large), small increases in volume lead to large increases in ICP or intracranial hypertension (Fig. 68-1). As ICP continues to increase, brain ischemia can occur as CPP falls. Further increases in ICP can ultimately displace the brain downward into the foramen magnum—a process called cerebral herniation, which can become irreversible in minutes and may lead to severe disability or death; Figure 68-2 notes other sites of brain herniation.

Oxygen and glucose are required by brain cells for normal functioning, and these nutrients must be constantly supplied by cerebral blood flow (CBF). Normally, CBF is constant over a wide range of blood pressures (blood pressure autoregulation of CBF) via actions mainly within the cerebral arterioles. Cerebral arterioles are maximally dilated at lower blood pressures and maximally constricted at higher pressures so that CBF does not vary during normal fluctuations (Fig. 68-3). Acid–base balance of the CSF (often reflected by acute changes in arterial partial pressure of carbon dioxide [PaCO₂]), body/brain temperature, glucose utilization, and other vasoactive mediators (i.e., adenosine, nitric oxide) can also affect the cerebral vasculature.

Figure 68-1 The Munro-Kellie doctrine describes intracranial dynamics in the setting of an expanding mass lesion (i.e., hemorrhage, tumor) or brain edema. In the normal state, the brain parenchyma, arterial blood, CSF, and venous blood occupy the cranial vault at a low pressure, generally <10 mm Hg. With an expanding mass lesion or brain edema, initially there is a compensated state as a result of reduced CSF and venous blood volumes, and ICP remains low. Further expansion of the lesion, however, leads to an uncompensated state when compensatory mechanisms are exhausted and intracranial hypertension results. See text for details.

Figure 68-2 Different forms of brain herniation. 1, Cingulate. 2, Uncal. 3, Cerebellar tonsillar. 4, Upward cerebellar. 5, Transcalvarial. (From Fishman RA: Cerebrospinal fluid in diseases of the nervous system, Philadelphia, 1980, Saunders.)

Figure 68-3 Schematic of the relationship between CBF and CPP. The diameter of a representative cerebral arteriole is also shown across the center of the y axis to facilitate understanding of the vascular response across CPP that underlies blood pressure autoregulation of CBF. CPP is generally defined as the mean arterial pressure (MAP) minus the ICP. At normal values for ICP, this generally represents MAP. Thus, normally, CBF is kept constant between the lower limit and upper limit of autoregulation; in normal adults, these values are ≈50 mm Hg and 150 mm Hg, respectively. In children, the upper limit of autoregulation is likely proportionally lower than the adult value relative to normal MAP for age. However, according to the work of Vavilala et al. (2003), lower limit values are surprisingly similar in infants and older children. Thus, infants and young children may have less reserve for adequate CPP. See text for details.
Knowledge of these concepts is instrumental to preventing secondary brain injury. Increases in CSF pH that occur because of inadvertent hyperventilation (decreased Paco₂) can produce cerebral ischemia. Hyperthermia-mediated increases in cerebral metabolic demands may damage vulnerable brain regions after injury. Hypoglycemia can produce neuronal death when CBF fails to compensate. Prolonged seizures can lead to permanent injuries if hypoxemia occurs from loss of airway control.

Attention to detail and constant reassessment are paramount in managing children with critical neurologic insults. Among the most valuable tools for serial, objective assessments of neurologic condition is the Glasgow Coma Scale (GCS) (see Table 67-3 in Chapter 67). Originally developed to assess level of consciousness after traumatic brain injury (TBI) in adults, the GCS is also valuable in pediatrics. Modifications to the GCS have been made for nonverbal children and are available for infants and toddlers (see Table 67-3 in Chapter 67). Serial assessments of the GCS score along with a focused neurologic examination are invaluable to detection of injuries before permanent damage occurs in the vulnerable brain.

The FOUR (full outline of unresponsiveness) score (Table 68-1) is a modification of the GCS, which eliminates the verbal response but adds two functional assessments of the brain stem (pupil, corneal, cough reflexes, and respiratory patterns).

The most-studied monitoring device in clinical practice is the ICP monitor. Monitoring is accomplished by a catheter inserted either into the cerebral ventricle (externalized ventricular drain) or into brain parenchyma (parenchymal transducer). ICP-directed therapies are standard of care in TBI and are used in other conditions, such as intracranial hemorrhage. Rye syndrome, and some cases of encephalopathy, meningitis, and encephalitis. Other devices being used include catheters that measure brain tissue oxygen concentration, external probes that noninvasively assess brain oxygenation by absorbance of near-infrared light (near-infrared spectroscopy), monitors of brain electrical activity (continuous electroencephalography [EEG] or somatosensory, visual, or auditory evoked potentials), and CBF monitors (transcranial Doppler, xenon CT, perfusion MRI, or tissue probes).

In the current severe TBI guidelines, brain tissue oxygen concentration monitoring received level III support and thus, may be considered.

### Traumatic Brain Injury

#### Etiology

Mechanisms of TBI include motor vehicle crashes, falls, assaults, and abusive head trauma. Most TBIs in children are from closed-head injuries.

#### Epidemiology

TBI is an important pediatric public health problem, with approximately 37,000 cases resulting in the death of more than 7,000 children annually in the United States.

#### Pathology

Epidural, subdural, and parenchymal intracranial hemorrhages can result. Injury to gray or white matter is also commonly seen and includes focal cerebral contusions, diffuse cerebral swelling, axonal injury, and injury to the cerebellum or brainstem. Patients with severe TBI often have multiple findings; diffuse and potentially delayed cerebral swelling is common.

#### Pathogenesis

TBI results in primary and secondary injury. Primary injury from the impact produces irreversible tissue disruption. In contrast, 2 types of secondary injury are targets of neurointensive care. First, some of the ultimate damage seen in the injured brain evolves over hours or days, and the underlying mechanisms involved (edema, apoptosis, and secondary axotomy) are therapeutic targets. Second, the injured brain is vulnerable to additional insults because injury disrupts normal autoregulatory defense mechanisms; disruption of autoregulation of CBF can lead to ischemia from hypotension that would otherwise be tolerated by the uninjured brain.

### Clinical Manifestations

The hallmark of severe TBI is coma (GCS score 3-8). Often, coma is seen immediately after the injury and is sustained. In some cases, such as with an epidural hematoma, a child may be alert on presentation but may deteriorate after a period of hours. A similar picture can be seen in children with diffuse swelling, in whom a talk-and-die scenario has been described. Clinicians should also not be lulled into underappreciating the potential for deterioration of a child with moderate TBI (GCS score 9-12) with a significant contusion, because progressive swelling can potentially lead to devastating complications. In the comatose child with severe TBI, the second key clinical manifestation is the development of intracranial hypertension. The development of increased ICP with impending herniation may be heralded by new-onset or worsening headache, depressed level of consciousness, vital sign changes (hypertension, bradycardia, irregular respirations), and signs of 6th (lateral rectus palsy) or 3rd (anisocoria [dilated pupil], ptosis, down-and-out position of globe as a result of rectus muscle palsies) cranial nerve compression. Increased ICP is managed with continuous ICP monitoring, as well as monitoring for clinical signs of increased ICP or impending herniation. The development of brain swelling is progressive. Significantly raised ICP (>20 mm Hg) can occur early after severe TBI, but peak ICP generally is seen at 48-72 hr.
Diagnosis and Differential Diagnosis

In severe TBI, the diagnosis is generally obvious from the history and clinical presentation. Occasionally, TBI severity can be overestimated because of concurrent alcohol or drug intoxication. The diagnosis of TBI can be problematic in cases of abusive head trauma or following an anoxic event such as drowning or smoke inhalation.

Treatment

Infants and children with severe or moderate TBI (GCS score 3-8 or 9-12, respectively) receive intensive care unit (ICU) monitoring. Evidence-based guidelines for management of severe TBI have been published (Fig. 68-12). This approach to ICP-directed therapy is also reasonable for other conditions in which ICP is monitored. Care involves a multidisciplinary team comprising pediatric caregivers from
neurologic surgery, critical care medicine, surgery, and rehabilitation, and is directed at preventing secondary insults and managing raised ICP. Initial stabilization of infants and children with severe TBI includes rapid sequence tracheal intubation with spine precautions along with maintenance of normal extracerebral hemodynamics, including blood gas values (partial pressure arterial oxygen, PaCO₂), mean arterial pressure, and temperature. Intravenous fluid boluses may be required to treat hypotension. Euvolemia is the target, and hypotonic fluids should be rigorously avoided; normal saline is the fluid of choice. Pressors may be needed as guided by monitoring of central venous pressure, with avoidance of both fluid overload and exacerbation of brain edema. A trauma survey should be performed. Once stabilized, the patient should be taken for CT scanning to rule out the need for emergency neurosurgical intervention. If surgery is not

**Figure 68-8** In a 3 mo old child who suffered from abusive head trauma, initial CT imaging (A) demonstrates chronic subdural hematoma bilaterally. Three days after hospitalization (B), the subdural hematomas are slightly larger but infarctions are noted in the posterior areas of brain parenchyma (see arrows).

**Figure 68-9** In a 16 yr old who fell off of his dirt bike, CT imaging demonstrates intraparenchymal hemorrhage and significant surrounding edema (arrow).

**Figure 68-10** An 11 yr old child was hit in the head by a horse, and CT imaging demonstrates multiple, comminuted skull fractures with fragments of bone within the brain parenchyma, multifocal areas of intraparenchymal hemorrhage, and obliteration of the left lateral ventricle.
pentobarbital and either mannitol (0.25-1.0 g/kg IV) or hypertonic saline (3% solution, 5-10 mL/kg IV). ICP should be maintained < 20 mm Hg; age-dependent CPP targets are ≈ 50 mm Hg for children 2-6 yr of age; 55 mm Hg for those 7-10 yr of age; and 65 mm Hg for those 11-16 yr of age. First-tier therapy includes elevation of the head of the bed, ensuring midline positioning of the head, controlled mechanical ventilation, and sedation and analgesia (i.e., benzodiazepines and narcotics). If neuromuscular blockade is needed, it may be desirable to monitor EEG continuously because status epilepticus can occur; this complication will not be recognized if treated promptly.

Figure 68-11 In a 6 yr old child who was hit by a car while riding his bike, initial CT imaging demonstrates no obvious abnormality (A). However, immediate MRI demonstrates multiple areas of punctate hemorrhages (lucencies) consistent with diffuse axonal injury (B, arrows).

Figure 68-12 Schematic outlining the approach to management of a child with severe TBI. It is based on the 2012 guidelines for the management of severe TBI, along with minor modifications from later literature. The ICP and CPP targets are discussed in the text. This schematic is specifically presented for severe TBI, for which the experience with ICP-directed therapy is greatest. Nevertheless, the general approach provided here is relevant to the management of intracranial hypertension in other conditions for which evidence-based data on ICP monitoring and ICP-directed therapy are lacking. Please see text for details.
in a paralyzed patient and is associated with raised ICP and unfavorable outcome. If a ventricular rather than parenchymal catheter is used to monitor ICP, therapeutic CSF drainage is available and can be provided either continuously (often targeting an ICP >5 mm Hg) or intermittently in response to ICP spikes, generally 20 mm Hg. Other first-tier therapies include the osmolar agents mannitol (0.25-1.0 g/kg IV over 20 min), given in response to ICP spikes >20 mm Hg or with a fixed (q4-6h) dosing interval, and hypertonic saline (often given as a continuous infusion of 3% saline at 0.1-1.0 mL/kg/hr). Choice of osmolar agent depends on the preference of the treating center. These 2 agents can be used concurrently. It is recommended to avoid serum osmolality >320 mOsm/L. A Foley urinary catheter should be placed to monitor urine output.

If ICP remains refractory to treatment, careful reassessment of the patient is needed to rule out unrecognized hypercarbia, hypoxemia, fever, hypotension, hypoglycemia, pain, and seizures. Repeat imaging should be considered to rule out a surgical lesion. Guidelines-based second-tier therapies for refractory raised ICP are available, but evidence favoring a given second-tier therapy is limited. In some centers, decompressive craniectomy is used. Others use a pentobarbital infusion, with a loading dose of 5-10 mg/kg over 30 min followed by 5 mg/kg every hour for 3 doses and then maintenance with an infusion of 1 mg/kg/hr. Careful blood pressure monitoring is required because of the possibility of drug-induced hypotension and the frequent need for support with fluids and/or pressors. Mild hypothermia (32–34°C [89.6–93.2°F]) to control refractory ICP can be induced and maintained by means of surface cooling. Sedation and neuromuscular blockade are used to prevent shivering, and rewarming should be slow, no faster than 1°C (1.8°F) every 4-6 hr. Hypotension should be prevented during rewarming. Refractory raised ICP can also be treated with hyperventilation (Paco₂ = 25-30 mm Hg). Other second-tier therapies (e.g., lumbar CSF drainage) are options.

Supportive Care
Euvolemic should be maintained, and isotonic fluids are recommended until resolution of intracranial hypertension. The syndrome of inappropriate antidiuretic hormone secretion and salt wasting can develop and are important to differentiate, because management of the former is fluid restriction and that of the latter is sodium replacement. Severe hyperglycemia (blood glucose level >200 mg/dL) should be avoided and treated. The blood glucose level should be monitored frequently. Early nutrition with enteral feedings is advocated. Corticosteroids should generally not be used unless adrenal insufficiency is documented. Tracheal suctioning can exacerbate raised ICP. Timing of the use of sedation around suctioning events and/or use of tracheal or IV lidocaine can be helpful. Seizures are common after severe acute TBI. Early posttraumatic seizures (within 1 wk) will complicate management of TBI and are often difficult to treat. Anticonvulsant prophylaxis with fosphenytoin, carbamazepine, or levetiracetam is a common treatment option. Late posttraumatic seizures (≥7 days after TBI) and, if recurrent, late posttraumatic epilepsy are not prevented by prophylactic anticonvulsants, whereas early posttraumatic seizures are prevented by initiating anticonvulsants soon after TBI. Antifibrinolytic agents (tranexamic acid) reduce hemorrhage size as well as the development of new focal ischemic cerebral lesions, and improve survival in adults with severe traumatic brain injury.

Prognosis
Mortality rates for children with severe TBI who reach the pediatric ICU range between 10% and 30%. Ability to control ICP is related to patient survival, and the extent of cranial and systemic injuries correlates with quality of life. Motor and cognitive sequelae resulting from severe TBI generally benefit from rehabilitation to minimize long-term disabilities. Recovery from TBI may take months to achieve. Physical therapy, and in some centers methylphenidate, helps with motor and behavioral recovery. Pituitary insufficiency may be an uncommon but significant complication of severe TBI.

Brain death is the irreversible cessation of all functions of the entire brain, including the brainstem. It is also known as the determination of death using neurologic criteria. Although brain death is legally accepted in the United States as the equivalent of death from the irreversible cessation of circulatory and respiratory functions, it can be difficult to understand and is not universally accepted.

Epidemiology
In children, brain death most commonly develops following TBI (including brain injury from nonaccidental trauma) or asphyxial injury. Pathogenesis is multifactorial, with the end result being irreversible loss of brain and brainstem function.

Clinical Manifestations and Diagnosis
Guidelines for the determination of brain death in children were first published in 1987 by a Special Task Force to the American Academy of Pediatrics. These were revised for the first time in 2011 by a combined group from the Society for Critical Care Medicine, the American Academy of Pediatrics, and the Child Neurology Society.

Brain death is primarily a clinical diagnosis. Although ancillary tests such as EEG and CBF studies are sometimes used to assist in making the diagnosis, repeated clinical examination is the standard for diagnosis. The 3 key components of clinical brain death diagnosis are demonstrations of coexisting irreversible coma with a known cause, absence of brainstem reflexes, and apnea.

Before a determination of brain death may be made, it is of utmost importance that the cause of the coma be determined through the use of historical, radiologic, and laboratory data to rule out a reversible condition. Potentially reversible causes of coma include metabolic disorders; toxins; sedative drugs; paralytic agents; hypothermia; hypoxia; hypotension/shock; recent cardiopulmonary resuscitation; hypoglycemia/hyperglycemia; hyponatremia/hypernatremia; hypercalcemia; hypermagnesemia; nonconvulsive status epilepticus; hypothryoidism; hypocortisolism; hypercarbia; liver or renal failure; sepsis; meningitis; encephalitis; subarachnoid hemorrhage; and surgically remediable brainstem lesions. Confounding factors must be corrected prior to initiation of brain death assessment.

Coma
The state of coma requires that the patient be unresponsive, even to noxious stimuli. Any purposeful motor response, such as localization, does not constitute coma. Likewise, any posturing (decerebrate or decorticate) is not consistent with coma, and therefore not consistent with brain death. The presence of spinal cord reflexes—even complex reflexes—does not preclude the diagnosis of brain death.

Brainstem Reflexes
Brainstem reflexes must be absent. Table 68-2 lists the brainstem reflexes to be tested, the brainstem location of each reflex, and the result of each test that is consistent with a diagnosis of brain death.

Apnea
Apnea is the absence of respiratory effort in response to an adequate stimulus. A partial pressure of carbon dioxide (pCO₂) value >260 mm Hg and >20 mm Hg above baseline is considered sufficient. Apnea is clinically confirmed through the apnea test. Because the apnea test has the potential to destabilize the patient, this test is performed only if the first 2 criteria for brain death (irreversible coma and absence of brainstem reflexes) are already confirmed.

The apnea test assesses the function of the medulla in driving ventilation. It is performed by first ensuring appropriate hemodynamics and temperature and the absence of apnea-producing drug effects or significant metabolic derangements. The patient is then preoxygenated with 100% oxygen for approximately 10 minutes and ventilation is adjusted to achieve a pCO₂ of approximately 40 mm Hg. A baseline

CN, cranial nerve.

blood gas result documents the starting values. During the test, oxygenation can be maintained with 100% oxygen via a T-piece attached to the endotracheal tube or via a resuscitation bag such as a Mapleson device. Throughout the test, the child’s hemodynamics and oxygen saturation are monitored while the physician observes for respiratory efforts. A blood gas sample is obtained approximately 10 min into the test and every 5 min thereafter until the target pCO₂ is surpassed; ventilatory support is resumed at that time. If at any point during the test the patient becomes hypoxic or hypotensive, the test is aborted and ventilatory support is resumed. Absence of respiratory efforts with a pCO₂ ≥60 mm Hg and >20 mm Hg above baseline is consistent with brain death.

OBSERVATION PERIODS
To establish the diagnosis of brain death, the findings must remain consistent for 2 examinations separated by an observation period. Recommended observation periods are 24 hr for neonates from 37 wk gestation to term infants 30 days old, and 12 hr for infants and children older than 30 days. An observation period of 24-48 hr prior to initiation of brain death assessment is recommended following CPR or severe acute brain injury.

ANCILLARY STUDIES
Ancillary studies are not required for the diagnosis of brain death unless the clinical examination including the apnea test cannot be safely or reliably completed. Examples include cervical spinal cord injury, presence of high-therapeutic or supratherapeutic levels of sedative medications, or hemodynamic instability or desaturation during an apnea test. Ancillary studies may also be used to shorten the recommended observation period. In this case, 2 complete clinical examinations, including apnea test, should be completed and documented along with the ancillary study.

The 2 most commonly used ancillary tests are EEG and radionuclide CBF studies. A valid EEG to support suspected brain death must be performed according to accepted technical requirements, under conditions of normothermia and appropriate hemodynamics, and in the absence of drug levels sufficient to suppress the EEG response. An EEG that demonstrates electrocerebral silence over a 30 min recording time under these conditions supports the diagnosis of brain death. Advantages of this study are its wide availability and low risk. Disadvantages include potential confounders, such as artifact in the tracing and the presence of suppressing levels of drugs such as barbiturates.

A radionuclide CBF study consists of intravenous injection of a radiopharmaceutical agent followed by imaging of the brain to look for cerebral uptake. Like EEG, nuclear medicine scans are widely available and low risk. Unlike EEG, these studies are not affected by drug levels. A study that shows absence of uptake in the brain demonstrates absence of CBF and is supportive of brain death. Four-vessel intracranial contrast angiography was previously used as the definitive ancillary test, but practical technical difficulties and risks have led to the use of nuclear medicine scans instead.

Interpretation of both EEG and radionuclide CBF studies should be done by appropriately trained and qualified individuals. If the studies show electrical activity or presence of CBF, brain death cannot be declared. A 24 hr waiting period is recommended prior to repeating the clinical examination or ancillary study.

DOCUMENTATION
Documentation is an important aspect of diagnosing brain death. Complete documentation should include statements of the following:
1. Etiology and irreversibility of the coma.
2. Absence of confounding factors: hypothermia, hypotension, hypoxia, significant metabolic derangement, significant drug levels.
3. Absence of motor response to noxious stimulation.
5. Absence of respiratory effort in response to an adequate stimulus; blood gas values should be documented at the beginning and end of the apnea test.

SUPPORTIVE CARE
Following a diagnosis of brain death, supportive care may continue for hours to days as the family makes decisions about potential organ donation and comes to terms with the diagnosis. A diagnosis of brain death may not be accepted by the family for personal, religious, or
cultural reasons. It is important for care providers to be patient and supportive of the family dealing with this difficult situation.

**OBJECTIONS TO THE IDEA OF BRAIN DEATH**

Although the concept of brain death is widely accepted and very useful in facilitating organ transplantation, it is not accepted by all. Several countries do not recognize brain death, and some individuals, both medical personnel and laypeople, object to the idea of brain death.

It has been pointed out that some patients who meet brain death criteria continue to show evidence of integrative functioning, such as control over free-water homeostasis (absence of diabetes insipidus), control of temperature regulation, capacity for growth and wound healing, and variability of heart rate and blood pressure in response to stimulus. Along with scientific arguments, there are also philosophical arguments about what constitutes death and whether a person who lacks function of the brain, but not of the body, is truly dead.

Bibliography

Syncope is defined as a sudden transient loss of consciousness with inability to maintain postural tone. The most common cause of syncope in the normal pediatric population is neurocardiogenic syncope, also known as vasovagal syncope (Table 69-1). Although this type of syncope is very common in adolescence and has an excellent prognosis, other causes for loss of consciousness are more dangerous, thus syncope may be the first sign of more serious conditions (Table 69-2). Indeed, the occurrence of syncope may well be the pediatrician’s best opportunity to diagnose a life-threatening condition before the patient subsequently succumbs. The task of the clinician, therefore, is not only to counsel the family and the patient concerning the common form, but also to rule out a number of important life-threatening cardiac problems.

**EPIDEMIOLOGY**
Most syncope presents during adolescence, typically between 11 and 13 yr of age. The incidence is somewhat higher in girls than in boys. Approximately 25% of all young adults will have experienced at least 1 episode of neurocardiogenic syncope.

**MECHANISMS**
Syncope by whatever mechanism is caused by a lack of adequate cerebral blood flow with loss of consciousness and inability to see remain upright. The mechanisms underlying neurocardiogenic syncope are not completely understood but seem to involve some trigger event that leads to vasodilation, venous pooling in the lower part of the body, decreased cardiac filling with compensatory sinus tachycardia and sympathetic nervous system activity, and, finally, activation of cardiac C fibers leading to reflex bradycardia. The typical event is triggered by a variety of factors, such as disgust, the site of blood, other emotional reactions, particular smells, or simply prolonged standing (see Table 69-1). Most patients display a mixed picture with both blood pressure and heart rate changes. Prior to syncope, the blood pressure declines and the heart rate increases, and with loss of consciousness there is often significant bradycardia. Other patients display a principally vasopressor response with a drop in blood pressure as the most important feature. Still others primarily have a cardioinhibitory response in which sudden profound bradycardia or asystole occurs with little or no change in blood pressure prior to the event. Making the distinction between these various patterns leading

to syncope is important for treatment considerations. In any case, with loss of consciousness and the assumption of supine posture, venous return and atrial filling dramatically increases and adequate blood pressure returns quickly.

Primary cardiac causes of syncope (see Table 69-2) include arrhythmias (see Chapter 435) such as long QT syndrome, Wolff-Parkinson-White syndrome (particularly with atrial fibrillation), ventricular tachycardia, and occasionally supraventricular tachycardia. Ventricular tachycardia may be associated with hypertrophic cardiomyopathy, repaired congenital heart disease, or a genetic cause such as catecholaminergic polymorphous ventricular tachycardia. Other arrhythmias that may lead to syncope are bradycardias such as sinus node dysfunction and high-grade 2nd or 3rd degree atrioventricular (AV) block. Patients with congenital complete AV block may present with syncope. Syncope may also be caused by cardiac obstructive lesions, such as critical aortic stenosis, or coronary artery anomalies, such as an aberrant left coronary artery arising from the right sinus of Valsalva. Finally, patients with primary pulmonary hypertension or Eisenmenger syndrome may experience syncope. In all of the obstructive forms of syncope, exercise increases the likelihood of an episode as the obstruction interferes with the ability of the heart to increased cardiac output in response to exercise.

Noncardiac causes of loss of consciousness include epilepsy, but may also include basilar artery migraine, hysterical syncope, and pseudo-seizures (see Table 69-1). Occasionally patients with narcolepsy may present as syncope. Hypoglycemia and hyperventilatation may also present with syncope.

**EVALUATION**

The most important goal in the evaluation of the new patient with syncope is to diagnose life-threatening causes of syncope so that these causes can be managed. Many patients presenting with sudden cardiac arrest caused by conditions such as long QT syndrome will have previously experienced an episode of syncope, and so the presentation with syncope is an opportunity to prevent sudden death.

The most important tool in evaluation is a careful history. The patient with neurocardiogenic syncope will be able to describe the circumstances of the event and specific prodromal symptoms. Typically, the patient will have been standing for a period of time, often on a hot day, or has gotten up suddenly from sleep or resting in a supine position. Occurrence in the shower is common, presumably caused by standing and vasodilation caused by hot water. For boys, the occurrence while urinating while standing is sometimes reported. The occurrence of syncope in girls while sitting or standing and having their hair brushed is common. Typical prodromal symptoms prior to syncope include lightheadedness, dizziness, nausea, sweating, and feeling hot or cold. Patients may report visual field changes and “rushing” in their ears. Witnesses will usually note extreme pallor or a gray color change. Injury to the patient as a result of the episode of syncope is unusual in common syncope, as the patient usually has adequate prodromal symptoms to avoid injury. Loss of consciousness is generally transient once the patient becomes supine; the loss of consciousness resolves rapidly (seconds to minutes), and there is no clear postevent state of sleepiness. Often, patients will describe other episodes with similar prodromal symptoms which did not lead to complete loss of consciousness but were aborted, often because the patient was able to assume recumbent posture. Some patients have a few tonic–clonic movements while unconscious, which resolve within seconds, and do not signify a seizure disorder.

The characteristics of cardiac syncope not due to neurocardiogenic mechanisms are generally quite different. A number of “red flags” can be identified that should lead the clinician to be suspicious that the mechanism is a life-threatening cardiac cause rather than simple fainting (Table 69-3). The occurrence during exercise suggests an arrhythmia or coronary obstruction. Injury as a result of an episode of syncope suggests sudden occurrence with a lack of adequate prodromal symp- toms, and suggests an arrhythmia. The occurrence of syncope while recumbent would be quite unusual in a patient with neurocardiogenic syncope and therefore raises the possibility of a cardiac or neurologic cause. Occasionally, a patient with syncope caused by a tachyarrhythmia will report the sensation of a racing heart prior to the event, but this is actually unusual.

A careful family history is essential in evaluation of syncope. Specifically, if there are first-degree relatives with inherited syndromes, such as a long QT syndrome or hypertrophic cardiomyopathy, this should lead to more specific evaluation of the patient. Also, if there are relatives who have died suddenly in young age without a clear and convincing cause, inherited cardiac arrhythmias or cardiomyopathies should also be suspected.

Patients with a history of heart disease, especially cardiac repair, may have causes that are specific to their repair. Sinus node dysfunction is common after the Senning or Mustard procedure for transposition of the great vessels. Ventricular tachycardia may be seen following repair of tetralogy of Fallot. A patient with a history of septal defect repair should be evaluated for the late occurrence of AV block, and patients with an implanted pacemaker should be evaluated for pacemaker lead failure.

The physical examination may also offer clues (see Table 69-3). Patients with hypertrophic cardiomyopathy may have a prominent cardiac impulse and/or an ejection murmur, as will patients with aortic stenosis. The patient with primary pulmonary hypertension will have a loud and single second heart sound and may also have an ejection click and the murmur of pulmonary insufficiency. Scars from prior cardiac surgery and pacemaker implantation would be evident.

All patients presenting with a first episode of syncope should have an electrocardiogram obtained, looking primarily for QT interval prolongation, preexcitation, ventricular hypertrophy, T-wave abnormalities, and conduction abnormalities. Other tests that may be needed depending on the results of the initial evaluation may include echocardiography, cardiac MRI, or 24-hr Holter monitoring. In patients for whom there is a strong suspicion of a paroxysmal arrhythmia, an implantable loop recorder may be the most effective means of diagnosis.

Tilt-table testing was originally developed by the military and was applied to the general population of otherwise normal individuals who have experienced syncope. While patients with neurocardiogenic syncope often will experience an episode during the tilt-table test, the test is poorly reproducible and neither particularly sensitive nor

specific. The use of tilt-table testing for the otherwise normal adolescent with simple fainting is discouraged. Some pediatric cardiologists still employ the test in severely affected individuals who are not responding to standard therapy, as a way of planning more aggressive therapy.

Additional tests to look for anemia, hypoglycemia, drugs of abuse, and other etiologies noted in Table 69-1 will be determined by the history and physical exam.

**TREATMENT**

Most patients with neurocardiogenic syncope will experience eventual resolution by adulthood; many even get better spontaneously within a few months or years. Many therapies have been employed for this condition, but it is difficult to determine which ones are truly effective because of the lack of randomized prospective studies. Nonetheless, initial salt and water supplementation is commonly recommended, particularly in those who have a low-salt diet or who have limited their fluid intake. A reasonable second step is treatment with fludrocortisone, a mineralocorticoid that promotes sodium and water retention with potassium loss. In patients who have a prominent low-blood-pressure response, the α-agonist midodrine may be useful. Both midodrine and fludrocortisone should be managed with careful monitoring of the supine blood pressure, as they may lead to supine hypertension. Some have advocated the use of β blockers such as, pindolol, which offers some advantages because of its intrinsic sympathomimetic activity; randomized prospective trials have not supported the effectiveness of beta blockers. Occasionally, the use of selective serotonin reuptake inhibitors is effective in certain patients.Occasional patients who present with profound bradycardia or asystole can be helped by implantation of a dual-chamber transvenous pacemaker with programmed hysteresis (rapid pacing in response to a sudden drop in heart rate).

The most important therapeutic step is educational. Once the young patient is aware of the importance of the prodromal symptoms, they can take appropriate steps to change position and not attempt to remain standing. In many, this is all that is necessary to adequately manage their symptoms.

### 69.1 Disorders of Orthostatic Intolerance

*George F. Van Hare*

Postural orthostatic tachycardia syndrome (POTS) is a female-predominant condition in which the patient experiences an impressive and symptomatic elevation in heart rate on standing. This orthostatic intolerance disorder manifests with presyncopal symptoms, lightheadedness, dizziness, palpitations, leg weakness and tremulousness on standing. An orthostatic heart rate of >120 beats/min and a rise in heart rate of ≥30 beats/min with 5 min of standing suggest the diagnosis. This should not be confused with neurocardiogenic syncope. Patients with POTS often also complain of other symptoms, such as fatigue, chest pain, headaches, abdominal pain, bloating, nausea, emesis, sleep disturbances, and fatigue. There is an overlap with patients with POTS and chronic fatigue syndrome or functional gastrointestinal disorders. Many patients are evaluated in dysautonomia programs and may have evidence of a small fiber polyneuropathy. Treatment of POTS is symptomatic and often not particularly successful. The use of β blockers may be effective; some physicians have advised increase physical activity through cardiac rehabilitation.

Juvenile-onset widespread pain syndromes associated with a small fiber polyneuropathy (dysautonomia) have associated gastrointestinal, cardiovascular, fatigue, headache symptoms as well as erythromelalgia. Steroids or intravenous immunoglobulin has been used to treat this disorder.

Bibliography
Shock is an acute process characterized by the body’s inability to deliver adequate oxygen to meet the metabolic demands of vital organs and tissues. Insufficient oxygen at the tissue level is unable to support normal aerobic cellular metabolism, resulting in a shift to less-efficient anaerobic metabolism. As shock progresses, increases in tissue oxygen extraction are unable to compensate for this deficiency in oxygen delivery, leading to progressive clinical deterioration and lactic acidosis. If inadequate tissue perfusion persists, adverse vascular, inflammatory, metabolic, cellular, endocrine, and systemic responses worsen physiologic instability.

Compensation for inadequate oxygen delivery involves a complex set of responses that attempt to preserve oxygenation of the vital organs (i.e., brain, heart, kidneys, liver) at the expense of other organs (i.e., skin, gastrointestinal tract, muscles). Of importance, the brain is especially sensitive to periods of poor oxygen supply, given its lack of capacity for anaerobic metabolism. Initially, shock is often well compensated, but it may rapidly progress to an uncompensated state requiring more aggressive therapies to achieve clinical recovery or improvement. The combination of a continued presence of an inciting trigger and the body’s exaggerated and potentially harmful neurohumoral, inflammatory, and cellular responses leads to the progression of shock. Irrespective of the underlying cause of shock, the specific pattern of response, pathophysiology, clinical manifestations, and treatments may vary significantly, depending on the specific etiology (which may be unknown), the clinical circumstances, and an individual patient’s biologic response to the shock state. Untreated shock causes irreversible tissue and organ injury (i.e., irreversible shock) and, ultimately, death.

**EPIDEMIOLOGY**

Shock occurs in approximately 2% of all hospitalized infants, children, and adults in developed countries, and the mortality rate varies substantially depending on the etiology and clinical circumstances. Most patients who do not survive, do not die in the acute hypotensive phase of shock, but rather as a result of associated complications and multiple organ dysfunction syndrome (MODS). MODS is defined as any alteration of organ function that requires medical support for maintenance, and the presence of MODS in patients with shock substantially increases the probability of death. In pediatrics, educational efforts and the utilization of standardized management guidelines that emphasize early recognition and intervention along with the rapid transfer of critically ill patients to a pediatric intensive care unit have led to decreases in the mortality rate for shock (Fig. 70-1).

**DEFINITION**

Shock classification systems generally define 5 major types of shock: hypovolemic, cardiogenic, distributive, obstructive, and septic (Table 70-1). **Hypovolemic shock**, the most common cause of shock in children worldwide, is most frequently caused by diarrhea, vomiting, or hemorrhage. **Cardiogenic shock** is seen in patients with either congenital heart disease (before or after surgery, including heart transplantation) or with congenital or acquired cardiomyopathies, including acute myocarditis. **Obstructive shock** stems from any lesion that creates a mechanical barrier that impedes adequate cardiac output, which include pericardial tamponade, tension pneumothorax, pulmonary embolism, and ductus-dependent congenital heart lesions. **Distributive shock** is caused by inadequate vasomotor tone, which leads to capillary leak and maldistribution of fluid into the interstitium. **Septic shock** is often discussed synonymously with distributive shock, but the septic process usually involves a more complex interaction of distributive, hypovolemic, and cardiogenic shock.
Chapter 70 • Shock

**Pathophysiology**

An initial insult triggers shock, leading to inadequate oxygen delivery to organs and tissues. Compensatory mechanisms attempt to maintain blood pressure by increasing cardiac output and systemic vascular resistance (SVR). The body also attempts to optimize oxygen delivery to the tissues by increasing oxygen extraction and redistributing blood flow to the brain, heart, and kidneys at the expense of the skin and gastrointestinal tract. These responses lead to an initial state of compensated shock, in which blood pressure is maintained. If treatment is not initiated or is inadequate during this period, decompensated shock develops, with hypotension and tissue damage that may lead to multisystem organ dysfunction and ultimately death (Fig. 70-2, Tables 70-2 and 70-3).

In the early phases of shock, multiple compensatory physiologic mechanisms act to maintain blood pressure and preserve tissue perfusion and oxygen delivery. Cardiovascular effects include increases in heart rate, stroke volume, and vascular smooth muscle tone, which are regulated through sympathetic nervous system activation and
The Types of Shock

**HYPOVOLEMIC**
- Decreased preload secondary to internal or external losses

**CARDIOGENIC**
- Cardiac pump failure secondary to poor myocardial function

**DISTRIBUTIVE**
- Abnormalities of vasomotor tone from loss of venous and arterial capacitance

**SEPTIC**
- Encompasses multiple forms of shock
  - Hypovolemic: third spacing of fluids into the extracellular, interstitial space
  - Distributive: early shock with decreased afterload
  - Cardiogenic: depression of myocardial function by endotoxins

**OBSERVABLE**
- Decreased cardiac output secondary to direct impediment to right- or left-heart outflow or restriction of all cardiac chambers

**POTENTIAL ETIOLOGIES**
- Blood loss: hemorrhage, plasma loss: burns, nephrotic syndrome, water/electrolyte loss: vomiting, diarrhea
- Congenital heart disease: Cardiomyopathies: infectious or acquired, dilated or restrictive
- Anaphylaxis: Neurologic: loss of sympathetic vascular tone secondary to spinal cord or brainstem injury
- Bacterial: Viral
- Fungal
- Drugs
- Tension pneumothorax
- Pericardial tamponade
- Pulmonary embolism
- Anterior mediastinal masses
- Critical coarctation of the aorta

CO₂ production from poor tissue perfusion. Renal excretion of hydro-
via several mechanisms, with changes in heart rate, preload, afterload,
and myocardial contractility occurring separately or in combination
(Table 70-4). Hypovolemic shock is characterized primarily by fluid loss and decreased preload. Tachycardia and an increase in SVR are
the initial compensatory responses to maintain cardiac output and
systemic blood pressure. Without adequate volume replacement, hypo-
tension develops, followed by tissue ischemia and further clinical dete-
roration. When there is preexisting low plasma oncotic pressure
(casted by nephrotic syndrome, malnutrition, hepatic dysfunction,
acute severe burns, etc.), even further volume loss and exacerbation of
shock may occur because of endothelial breakdown and worsening
capillary leak.

In contrast, the underlying pathophysiologic mechanism leading to
distributive shock is a state of abnormal vasodilation and decreased
SVR. Sepsis, hypoxia, poisonings, anaphylaxis, spinal cord injury, or
mitochondrial dysfunction can cause vasodilatory shock (Fig. 70-3).
The lowering of SVR is accompanied initially by a maldistribution of
blood flow away from vital organs and a compensatory increase in
cardiac output. This process leads to significant decreases in both preload and afterload. Therapies for distributive shock must address
both of these problems simultaneously.

Cardiogenic shock may be seen in patients with myocarditis, car-
diomyopathy, congenital heart disease, or arrhythmias, or following
cardiac surgery (see Chapter 434). In these instances, myocardial con-
tractility is affected, leading to systolic and/or diastolic dysfunction.
The later phases of all forms of shock frequently have a negative impact
on the myocardium, leading to development of a cardiogenic compo-
nent to the shock state.

Septic shock is often a unique combination of distributive, hypovo-
lemic, and cardiogenic shock. Hypovolemia from intravascular fluid
losses occurs through capillary leak. Cardiogenic shock results from
the myocardial-depressant effects of sepsis, and distributive shock is
the result of decreased SVR. The degree to which a patient exhibits
each of these responses varies, but there are frequently alterations in
preload, afterload, and myocardial contractility.

In septic shock, it is important to distinguish between the inciting
infection and the host inflammatory response. Normally, host immu-
nity prevents the development of sepsis via activation of the reticular
endothelial system along with the cellular and humoral immune
systems. This host immune response produces an inflammatory
cascade of toxic mediators, including hormones, cytokines, and
enzymes. If this inflammatory cascade is uncontrolled, derangement of
the microcirculatory system leads to subsequent organ and cellular
dysfunction.

The systemic inflammatory response syndrome (SIRS) is an
inflammatory cascade that is initiated by the host response to an
Infectious or noninfectious trigger (Table 70-5). This inflammatory cascade is triggered when the host defense system does not adequately recognize and/or clear the triggering event. The inflammatory cascade initiated by shock can lead to hypovolemia, cardiac and vascular failure, acute respiratory distress syndrome (ARDS), insulin resistance, decreased cytochrome P450 activity (decreased steroid synthesis), coagulopathy, and unresolved or secondary infection. Tumor necrosis factor (TNF) and other inflammatory mediators increase vascular permeability, causing diffuse capillary leak, decreased vascular tone, and an imbalance between perfusion and metabolic demands of the tissues. TNF and interleukin (IL)-1 stimulate the release of proinflammatory and antiinflammatory mediators, causing fever and vasodilation. Proinflammatory mediators include IL-6, IL-12, interferon-γ, and macrophage migration inhibitory factor; antiinflammatory cytokines include IL-10, transforming growth factor-β, and IL-4. Arachidonic acid metabolites lead to the development of fever, tachypnea, ventilation-perfusion abnormalities, and lactic acidosis. Nitric oxide, released from the endothelium or inflammatory cells, is a major contributor to hypotension. Myocardial depression is caused directly by myocardial-depressant factors, TNF, and some interleukins, and further depressed via depleted catecholamines, increased β-endorphin, and production of myocardial nitric oxide.

The inflammatory cascade (Fig. 70-4) is initiated by toxins or superantigens via macrophage binding or lymphocyte activation. The vascular endothelium is both a target of tissue injury and a source of inflammatory mediators. The release of these mediators leads to an imbalance between perfusion and metabolic demands of the tissues. This imbalance results in the development of organ dysfunction, which can be assessed by a variety of criteria.

EXTRACORPOREAL FLUID LOSS
Hypovolemic shock may be a result of direct blood loss through hemorrhage or abnormal loss of body fluids (diarrhea, vomiting, burns, diabetes mellitus or insipidus, nephrosis)

LOWER PLASMA Oncotic FORCES
Hypovolemic shock may also result from hypoproteinemia (liver injury, or as a progressive complication of increased capillary permeability)

ABNORMAL VASODILATION
Distributive shock (neurogenic, anaphylaxis, or septic shock) occurs when there is loss of vascular tone—venous, arterial, or both (sympathetic blockade, local substances affecting permeability, acidosis, drug effects, spinal cord transection)

INCREASED VASCULAR PERMEABILITY
Sepsis may change the capillary permeability in the absence of any change in capillary hydrostatic pressure (endotoxins from sepsis, excess histamine release in anaphylaxis)

CARDIAC DYSFUNCTION
Peripheral hypoperfusion may result from any condition that affects the heart's ability to pump blood efficiently (ischemia, acidosis, drugs, constrictive pericarditis, pancreatitis, sepsis)
of mediators that may cause further injury. Biochemical responses include the production of arachidonic acid metabolites, release of myocardial depressant factors, release of endogenous opiates, activation of the complement system, as well as the production and release of many other mediators, which may be either proinflammatory or antiinflammatory. The balance between these mediator groups for an individual patient contributes to the progression of disease and affects the chance for survival.

**CLINICAL MANIFESTATIONS**

Table 70-1 shows a classification system for shock. Categorization is important, but there may be significant overlap among these groups, especially in septic shock. The clinical presentation of shock depends in part on the underlying etiology, but if unrecognized and untreated, all forms of shock follow a common and untoward progression of clinical signs and pathophysiologic changes that may ultimately lead to irreversible organ injury and death (see Fig. 70-2).

Shock may initially manifest as only tachycardia, with or without tachypnea. Progression leads to decreased urine output, poor peripheral perfusion, respiratory distress or failure, alteration of mental status, and low blood pressure (see Table 70-3). A significant misconception is that shock occurs only with low blood pressure; hypotension is often a late finding and is not a criterion for the diagnosis of shock because of a complex set of compensatory mechanisms attempting to preserve blood pressure. Hypotension reflects an advanced state of decompensated shock and is associated with increased morbidity and mortality.

**Hypovolemic shock** often manifests initially as orthostatic hypotension and is associated with dry mucous membranes, dry axillae, poor skin turgor, and decreased urine output. Depending on the degree of dehydration, the patient with hypovolemic shock may present with either normal or slightly cool distal extremities, and pulses may be normal, decreased, or absent depending on disease severity. The presenting signs of **cardiogenic shock** are tachycardia, cool extremities, delayed capillary filling time, poor peripheral and/or central pulses, declining mental status, and decreased urine output, caused by the combination of decreased cardiac output and compensatory peripheral

**Figure 70-3** Mechanisms of vasodilatory shock. Septic shock and states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate the adenosine triphosphate (ATP)–sensitive and calcium-regulated potassium channels (K$_{ATP}$ and K$_{Ca}$, respectively) in vascular smooth muscle, and lead to depletion of vasopressin. cGMP, cyclic guanosine monophosphate. (From Landry DW, Oliver JA: The pathogenesis of vasodilatory shock, N Engl J Med 345:588-595, 2001.)
Further deterioration leads to septic shock (severe sepsis plus the persistence of hypoperfusion or hypotension despite adequate fluid resuscitation or a requirement for vasoactive agents), MODS, and possibly death (Table 70-7). This is a complex spectrum of clinical problems that is a leading cause of mortality in children worldwide. This mortality can be mitigated and outcomes improved with early recognition and treatment.

Obstructive shock often also manifests as inadequate cardiac output because of a physical restriction of forward blood flow, and the acute presentation may quickly progress to cardiac arrest. Distributive shock manifests initially as peripheral vasodilation and increased but inadequate cardiac output. Regardless of etiology, uncompensated shock, with hypotension, high SVR, decreased cardiac output, respiratory failure, obtundation, and oliguria, occurs late in the progression of disease. Table 70-6 lists the hemodynamic findings in various shock states. Additional clinical findings in shock include cutaneous lesions such as petechiae, diffuse erythema, ecchymoses, ecthyma gangrenosum, and peripheral gangrene. Jaundice can be present either as a sign of infection or as a result of MODS.

Sepsis is defined as SIRS resulting from a suspected or proven infectious etiology. The clinical spectrum of sepsis begins when a systemic (e.g., bacteremia, rickettsial disease, fungemia, viremia) or localized (e.g., meningitis, pneumonia, pyelonephritis) infection progresses from sepsis to severe sepsis (the presence of sepsis combined with organ dysfunction). Further deterioration leads to septic shock (severe sepsis plus the persistence of hypoperfusion or hypotension despite adequate fluid resuscitation or a requirement for vasoactive agents), MODS, and possibly death (Table 70-7). This is a complex spectrum of clinical problems that is a leading cause of mortality in children worldwide. This mortality can be mitigated and outcomes improved with early recognition and treatment.

Although septic shock is primarily distributive in nature, multiple other elements of pathophysiology are represented in this disease process. The initial signs and symptoms of sepsis include alterations in temperature regulation (hyperthermia or hypothermia), tachycardia, and tachypnea. In the early stages (hyperdynamic phase, low SVR, or “warm” shock), cardiac output increases in an attempt to maintain adequate oxygen delivery and meet the greater metabolic demands of the organs and tissues. As septic shock progresses, cardiac output falls in response to the effects of numerous inflammatory mediators, leading to a compensatory elevation in SVR and the development of “cold” shock.
The Acutely Ill Child

incubation of cultures, and results often are not positive. Additional evidence for identifying an infectious etiology as the cause of SIRS includes physical examination findings, imaging, presence of white blood cells in normally sterile body fluids, and suggestive rashes such as petechiae and purpura. Affected children should be admitted to an intensive care unit or other highly monitored environment, as indicated by clinical status and the resources of the medical facility. These patients necessitate continuous monitoring, with a combination of

**DIAGNOSIS**

Shock is a clinical diagnosis based on a thorough history and physical examination (see Tables 70-2 and 70-3). Of note, septic shock has a specific consensus conference definition (see Table 70-7). In cases of suspected septic shock, an infectious etiology should be sought through culture of clinically appropriate specimens and prompt initiation of empiric antimicrobial therapy based on patient age, underlying disease, and geographic location, recognizing that time is necessary for

FIO₂, fraction of inspired oxygen; PaO₂, partial pressure arterial oxygen.
noninvasive (pulse oximetry, capnography, near infra-red spectroscopy) and invasive (central venous pressure, arterial blood pressure) techniques as clinically indicated.

**LABORATORY FINDINGS**

Laboratory findings often include evidence of hematologic abnormalities and electrolyte disturbances. Hematologic abnormalities may include thrombocytopenia, prolonged prothrombin and partial thromboplastin times, reduced serum fibrinogen level, elevations of fibrin split products, and anemia. Elevated neutrophil counts and increased immature forms (i.e., bands, myelocytes, promyelocytes), vacuolation of neutrophils, toxic granulations, and Döhle bodies can be seen with infection. Neutropenia or leukopenia may be an ominous sign of overwhelming sepsis.

Glucose dysregulation, a common stress response, may manifest as hyperglycemia or hypoglycemia. Other electrolyte abnormalities are hypocalcemia, hypoalbuminemia, and metabolic acidosis. Renal and/or hepatic function may also be abnormal. Patients with ARDS or pneumonia have impairment of oxygenation (decreased partial pressure arterial oxygen \([Pao_2]\)) as well as of ventilation (increased arterial partial pressure of carbon dioxide \([Paco_2]\)) in the later stages of lung injury (see Chapter 71).

The hallmark of uncompensated shock is an imbalance between oxygen delivery \((Do_2)\) and oxygen consumption \((Vo_2)\). Oxygen delivery normally exceeds oxygen consumption threefold. The oxygen extraction ratio is approximately 25%, thus producing a normal mixed venous oxygen saturation \((SV_o_2)\) of 75-80%. A falling \(SV_o_2\) value, as measured by cooximetry, reflects an increasing oxygen extraction ratio and documents a decrease in oxygen delivery relative to consumption. This increase in oxygen extraction by the end-organs is an attempt to maintain adequate oxygen delivery at the cellular level. This state is manifested clinically by increased lactic acid production (high anion gap, metabolic acidosis) caused by anaerobic metabolism and the compensatory increase in tissue oxygen extraction. The gold standard measurement of \(SV_o_2\) is from a pulmonary arterial catheter, but measurements from this location are often not clinically feasible. Sites such as the right ventricle, right atrium, superior vena cava \((SVCO_2)\), or inferior vena cava are often used as surrogate measures of mixed venous blood to follow the adequacy of oxygen delivery and effectiveness of therapeutic interventions. Elevated blood lactate levels reflect poor tissue oxygen delivery noted in all forms of shock.

**TREATMENT**

**Initial Management**

Early recognition and prompt intervention are extremely important in the management of all forms of shock (Tables 70-8 to 70-12). The vital sign targets and dose recommendations in Tables 70-9 to 70-11 should be adjusted to pediatric-size patients. Baseline mortality is much lower in pediatric shock than in adult shock, and further improvements in mortality are associated with early interventions (see Fig. 70-1). The initial assessment and treatment of the pediatric shock patient should include stabilization of airway, breathing, and circulation as established by the American Heart Association’s pediatric advanced life support and neonatal advanced life support guidelines (see Chapter 67). Depending on the severity of shock, further airway intervention, including intubation and mechanical ventilation, may be necessary to lessen the work of breathing and decrease the body’s overall metabolic demands.

Given the predominance of sepsis and hypovolemia as the most common causes of shock in the pediatric population, most therapeutic regimens are based on guidelines established in these settings. Immediately following establishment of intravenous (IV) or intraosseous...
Table 70-9 Recommendations: Initial Resuscitation and Infection Issues—Adults

INITIAL RESUSCITATION

1. Protocolized, quantitative resuscitation of patients with sepsis-induced tissue hypoperfusion (defined in this document as hypotension persisting after initial fluid challenge or blood lactate concentration ≥4 mmol/L). Goals during the 1st 6 hr of resuscitation:
   (a) Central venous pressure 8-12 mm Hg
   (b) Mean arterial pressure (MAP) ≥65 mm Hg
   (c) Urine output ≥0.5 mL kg⁻¹ hr⁻¹
   (d) Central venous (superior vena cava) or mixed venous oxygen saturation 70% or 65%, respectively
2. In patients with elevated lactate levels, targeting resuscitation to normalize lactate as rapidly as possible.

SCREENING FOR SEPSIS AND PERFORMANCE IMPROVEMENT

1. Routine screening of potentially infected seriously ill patients for severe sepsis to allow earlier implementation of therapy.
2. Hospital-based performance improvement efforts in severe sepsis.

DIAGNOSIS

1. Cultures as clinically appropriate before antimicrobial therapy if no significant delay (>45 min) in the start of antimicrobial(s). At least 2 sets of blood cultures (both aerobic and anaerobic bottles) be obtained before antimicrobial therapy with at least 1 drawn percutaneously and 1 drawn through each vascular access device, unless the device was recently (<48 hr) inserted.
2. Use of the 1,3 β-D-glucan assay, mannan and antimannan antibody assays, if available and invasive candidiasis is in differential diagnosis of cause of infection.
3. Imaging studies performed promptly to confirm a potential source of infection.

ANTIMICROBIAL THERAPY

1. Administration of effective intravenous antimicrobials within the first hour of recognition of septic shock and severe sepsis without septic shock as the goal of therapy.
2a. Initial empiric antinfecive therapy of one or more drugs that have activity against all likely pathogens (bacterial and/or fungal and/or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis.
2b. Antimicrobial regimen should be reassessed daily for potential deescalation.
3. Use of low procalcitonin levels or similar biomarkers to assist the clinician in the discontinuation of empiric antibiotics in patients who initially appeared septic, but have no subsequent evidence of infection.
4a. Combination empirical therapy for neutropenic patients with severe sepsis and for patients with difficult to treat, multidrug-resistant bacterial pathogens such as Acinetobacter and Pseudomonas spp.
4b. Empiric combination therapy should not be administered for more than 3-5 days. Deescalation to the most appropriate single therapy should be performed as soon as the susceptibility profile is known.
5. Duration of therapy typically 7-10 days; longer courses may be appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with Staphylococcus aureus; some fungal and viral infections or immunologic deficiencies, including neutropenia.
6. Antiviral therapy initiated as early as possible in patients with severe sepsis or septic shock of viral origin.
7. Antimicrobial agents should not be used in patients with severe inflammatory states determined to be of noninfectious cause.

SOURCE CONTROL

1. A specific anatomical diagnosis of infection requiring consideration for emergent source control be sought and diagnosed or excluded as rapidly as possible, and intervention be undertaken for source control within the 1st 12 hr after the diagnosis is made, if feasible.
2. When infected peripancreatic necrosis is identified as a potential source of infection, definitive intervention is best delayed until adequate demarcation of viable and nonviable tissues has occurred.
3. When source control in a severely septic patient is required, the effective intervention associated with the least physiologic insult should be used (e.g., percutaneous rather than surgical drainage of an abscess).
4. If intravascular access devices are a possible source of severe sepsis or septic shock, they should be removed promptly after other vascular access has been established.

INFECTION PREVENTION

1a. Selective oral decontamination and selective digestive decontamination should be introduced and investigated as a method to reduce the incidence of ventilator-associated pneumonia; this infection control measure can then be instituted in healthcare settings and regions where this methodology is found to be effective.
1b. Oral chlorhexidine gluconate be used as a form of oropharyngeal decontamination to reduce the risk of ventilator-associated pneumonia in ICU patients with severe sepsis.

Surviving Sepsis Campaign Care Bundles

To be completed within 3 hr:
1. Measure lactate level
2. Obtain blood cultures prior to administration of antibiotics
3. Administer broad-spectrum antibiotics
4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L

To be completed within 6 hr:
5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mm Hg
6. In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate ≥4 mmol/L (≥36 mg/dL)
7. Measure central venous pressure (CVP)*
8. Measure central venous oxygen saturation (ScvO₂)*
9. Remeasure lactate if initial lactate was elevated*

*Targets for quantitative resuscitation included in the guidelines are CVP of ≥8 mm Hg, ScvO₂ of ≥70%, and normalization of lactate.

Table 70-11

Recommendations: Hemodynamic Support and Adjunctive Therapy—Adults

**FLUID THERAPY OF SEVERE SEPSIS**
1. Crystalloids as the initial fluid of choice in the resuscitation of severe sepsis and septic shock.
2. Against the use of hydroxethyl starches for fluid resuscitation of severe sepsis and septic shock.
3. Albumin in the fluid resuscitation of severe sepsis and septic shock when patients require substantial amounts of crystalloids.
4. Initial fluid challenge in patients with sepsis-induced tissue hypoperfusion with suspicion of hypovolemia to achieve a minimum of 30 mL/kg of crystalloids (a portion of this may be albumin equivalent). More rapid administration and greater amounts of fluid may be needed in some patients.
5. Fluid challenge technique be applied wherein fluid administration is continued as long as there is hemodynamic improvement either based on dynamic (e.g., change in pulse pressure, stroke volume variation) or static (e.g., arterial pressure, heart rate) variables.

**VASOPRESSORS**
1. Vasopressor therapy initially to target a mean arterial pressure (MAP) of 65 mm Hg.
2. Norepinephrine as the first choice vasopressor.
3. Epinephrine (added to and potentially substituted for norepinephrine) when an additional agent is needed to maintain adequate blood pressure.
4. Vasopressin 0.03 units/min can be added to norepinephrine (NE) with intent of either raising MAP or decreasing NE dosage.
5. Low-dose vasopressin is not recommended as the single initial vasopressor for treatment of sepsis-induced hypotension and vasopressin doses higher than 0.03-0.04 units/min should be reserved for salvage therapy (failure to achieve adequate MAP with other vasopressor agents).
6. Dopamine as an alternative vasopressor agent to norepinephrine only in highly selected patients (e.g., patients with low risk of tachyarrhythmias and absolute or relative bradycardia).
7. Phenylephrine is not recommended in the treatment of septic shock except in circumstances where (a) NE is associated with serious arrhythmias, (b) cardiac output is known to be high and blood pressure persistently low, or (c) as salvage therapy when combined inotrope/vasopressor drugs and low-dose vasopressin have failed to achieve MAP target.
8. Low-dose dopamine should not be used for renal protection.
9. All patients requiring vasopressors have an arterial catheter placed as soon as practical if resources are available.

**INOTROPIC THERAPY**
1. A trial of dobutamine infusion up to 20 µg/kg/min be administered or added to vasopressor (if in use) in the presence of (a) myocardial dysfunction as suggested by elevated cardiac filling pressures and low cardiac output, or (b) ongoing signs of hypoperfusion, despite achieving adequate intravascular volume and adequate MAP.
2. Not using a strategy to increase cardiac index to predetermined supranormal levels.

**CORTICOSTEROIDS**
1. Not using intravenous hydrocortisone to treat adult septic shock patients if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability (see goals for Initial Resuscitation). In case this is not achievable, we suggest intravenous hydrocortisone alone at a dose of 200 mg per day.
2. Not using the ACTH stimulation test to identify adults with septic shock who should receive hydrocortisone.
3. In treated patients, hydrocortisone tapered when vasopressors are no longer required.
4. Corticosteroids should not be administered for the treatment of sepsis in the absence of shock.
5. When hydrocortisone is given, use continuous flow.

Table 70-12  Recommendations: Special Considerations in Pediatrics

### INITIAL RESUSCITATION
1. For respiratory distress and hypoxemia start with face mask oxygen or if needed and available, high flow nasal cannula oxygen or nasopharyngeal CPAP (NP CPAP). For improved circulation, peripheral intravenous access or intraosseous access can be used for fluid resuscitation and intrope infusion when a central line is not available. If mechanical ventilation is required then cardiovascular instability during intubation is less likely after appropriate cardiovascular resuscitation.
2. Initial therapeutic end points of resuscitation of septic shock: capillary refill of ≤2 sec, normal blood pressure for age, normal pulses with no differential between peripheral and central pulses, warm extremities, urine output >1 mL kg⁻¹ hr⁻¹, and normal mental status. ScvO₂ saturation ≥70% and cardiac index between 3.3 and 6.0 L/min/m² should be targeted thereafter.
3. Follow American College of Critical Care Medicine-Pediatric Life Support (ACCM-PALS) guidelines for the management of septic shock.
4. Evaluate for and reverse pneumothorax, pericardial tamponade, or endocrine emergencies in patients with refractory shock.

### ANTIBIOTICS AND SOURCE CONTROL
1. Empiric antibiotics should be administered within 1 hr of the identification of severe sepsis. Blood cultures should be obtained before administering antibiotics when possible but this should not delay administration of antibiotics. The empiric drug choice should be changed as epidemic and endemic ecologies dictate (e.g., H1N1, methicillin-resistant Staphylococcus aureus [MRSA], chloroquine-resistant malaria, penicillin-resistant pneumococci, recent ICU stay, neutropenia).
2. Clindamycin and antitoxin therapies for toxic shock syndromes with refractory hypotension.
3. Early and aggressive source control.
4. Clostridium difficile colitis should be treated with enteral antibiotics if tolerated. Oral vancomycin is preferred for severe disease.

### FLUID RESUSCITATION
1. In the industrialized world with access to inotropes and mechanical ventilation, initial resuscitation of hypovolemic shock begins with infusion of isotonic crystallloids or albumin with boluses of up to 20 mL/kg crystallloids (or albumin equivalent) over 5-10 minutes, titrated to reversing hypotension, increasing urine output, and attaining normal capillary refill, peripheral pulses, and level of consciousness without inducing hepatomegaly or rales. If hepatomegaly or rales exist then inotropic support should be implemented, not fluid resuscitation. In nonhypotensive children with severe hemolytic anemia (severe malaria or sickle cell crises), blood transfusion is considered superior to crystallloid or albumin bolus.

### INOTROPES/VASOPRESSORS/VASODILATORS
1. Begin peripheral inotropic support until central venous access can be attained in children who are not responsive to fluid resuscitation.
2. Patients with low cardiac output and elevated systemic vascular resistance states with normal blood pressure should be given vasodilator therapies in addition to inotropes.

### EXTRACORPOREAL MEMBRANE OXYGENATION (ECMO)
1. Consider ECMO for refractory pediatric septic shock and respiratory failure.

### CORTICOSTEROIDS
1. Timely hydrocortisone therapy in children with fluid refractory, catecholamine resistant shock and suspected or proven absolute (classic) adrenal insufficiency.

### PROTEIN C AND ACTIVATED PROTEIN CONCENTRATE
No recommendation as no longer available.

### BLOOD PRODUCTS AND PLasma THERAPIES
1. Similar hemoglobin targets in children as in adults. During resuscitation of low superior vena cava oxygen saturation shock (<70 %), hemoglobin levels of 10 g/dL are targeted. After stabilization and recovery from shock and hypoxemia, a lower target (>7.0 g/dL) can be considered reasonable.
2. Similar platelet transfusion targets in children as in adults.
3. Use plasma therapies in children to correct sepsis-induced thrombotic purpura disorders, including progressive disseminated intravascular coagulation, secondary thrombotic microangiopathy, and thrombotic thrombocytopenic purpura.

### MECHANICAL VENTILATION
1. Lung-protective strategies during mechanical ventilation.

### SEDATION/ANALGESIA/DRUG TOXICITIES
1. We recommend use of sedation with a sedation goal in critically ill mechanically ventilated patients with sepsis.
2. Monitor drug toxicity labs because drug metabolism is reduced during severe sepsis, putting children at greater risk of adverse drug-related events.

### GLYCEMIC CONTROL
1. Control hyperglycemia using a similar target as in adults (≤180 mg/dL). Glucose infusion should accompany insulin therapy in newborns and children because some hyperglycemic children make no insulin whereas others are insulin resistant.

### DIURETICS AND RENAL REPLACEMENT THERAPY
1. Use diuretics to reverse fluid overload when shock has resolved, and if unsuccessful then continuous venovenous hemofiltration (CVVH) or intermittent dialysis to prevent >10% total body weight fluid overload.

### DEEP VEIN THROMBOSIS (DVT) PROPHYLAXIS
No recommendation on the use of DVT prophylaxis in prepubertal children with severe sepsis.

### STRESS ULCER (SU) PROPHYLAXIS
No recommendation on the use of SU prophylaxis in prepubertal children with severe sepsis.

### NUTRITION
1. Enteral nutrition given to children who can be fed enterally, and parenteral feeding in those who cannot (grade 2C).

---

*CPAP, continuous positive airway pressure.

plus cefotaxime and/or gentamicin. Acyclovir should be added if herpes simplex virus is suspected clinically. In infants and children, community-acquired infections with Neisseria meningitidis can initially be treated empirically with a 3rd-generation cephalosporin (ceftriaxone or cefotaxime). Haemophilus influenzae infections can be treated empirically with a 3rd-generation cephalosporin (ceftriaxone or cefotaxime). The prevalence of resistant Streptococcus pneumoniae requires the addition of vancomycin. Suspicion of community- or hospital-acquired, methicillin-resistant Staphylococcus aureus infection warrants coverage with vancomycin, depending on local resistance patterns. If an intraabdominal process is suspected, anaerobic coverage should be included with an agent such as metronidazole, clindamycin, or piperacillin-tazobactam.

Nosocomial sepsis should generally be treated with at least a 3rd- or 4th-generation cephalosporin or a penicillin with an extended Gram-negative spectrum (e.g., piperacillin-tazobactam). An aminoglycoside should be added as the clinical situation warrants. Vancomycin should be added to the regimen if the patient has an indwelling medical device (see Chapter 179), Gram-positive cocci are isolated from the blood, methicillin-resistant S. aureus infection is suspected, or as empiric coverage for S. pneumoniae in a patient with meningitis. Empirical coverage for fungal infections should be considered for selected immuno compromised patients (see Chapter 178). It should be noted that these are broad, generalized recommendations that must be tailored to the individual clinical scenario and to the local resistance patterns of the community and/or hospital.

Distributive shock that is not secondary to sepsis is caused by a primary abnormality in vascular tone. Cardiac output in affected patients is usually maintained and may initially be supranormal. These patients may benefit temporarily from volume resuscitation, but the early initiation of a vasoconstrictive agent to increase SVR is important element of clinical care. Patients with spinal cord injury and spinal shock may benefit from either phenylephrine or vasopressin to increase SVR, and epinephrine is the treatment of choice for patients with anaphylaxis (Table 70-13). Epinephrine has peripheral α-adrenergic as well as inotropic effects that may improve the myocardial depression seen with anaphylaxis and its associated inflammatory response (see Chapter 149).

Patients with cardiogenic shock have poor cardiac output secondary to systolic and/or diastolic myocardial depression, often with a compensatory elevation in SVR. These patients may show poor response to fluid resuscitation and may decompensate quickly when fluids are administered. Smaller boluses of fluid (5-10 mL/kg) should be given in cardiogenic shock to replace deficits and maintain preload. In any patient with shock whose clinical status deteriorates with fluid resuscitation, a cardiogenic etiology should be considered, and further administration of intravenous fluids should be provided judiciously. Early initiation of myocardial support with epinephrine or dopamine to improve cardiac output is important in this context and early consideration should be given to administration of inodilator, such as milrinone.

Despite adequate cardiac output with the support of inotropic agents, a high SVR with poor peripheral perfusion and acidosis may persist in cardiogenic shock. Therefore, if not already started, milrinone therapy may improve systolic function and decrease SVR without causing a significant increase in heart rate. Furthermore, this agent has the added benefit of enhancing diastolic relaxation. Dobutamine or other vasodilating agents, such as nitroprusside, may also be considered in this setting (Table 70-14). Titration of these agents should target clinical end points, including increased urine output, improved peripheral perfusion, resolution of acidosis, and normalization of mental status. Even though they may be beneficial in other forms of shock, agents that improve blood pressure by increasing SVR, such as norepinephrine and vasopressin, should generally be avoided in patients with cardiogenic shock. These agents may cause further decomposition and potentially precipitate cardiac arrest as a result of the increased afterload and additional work imposed on the myocardium. The combination of inotropic and vasoactive agents must be tailored to the pathophysiology of the individual patient with close and frequent reassessment of the patient’s cardiovascular status.

For patients with obstructive shock, fluid resuscitation may be briefly temporizing in maintaining cardiac output, but the primary insult must be immediately addressed. Examples of lifesaving therapeutic interventions for such patients are pericardiocentesis for pericardial effusion, pleurocentesis or chest tube placement for pneumothorax, thrombectomy/thrombolysis for pulmonary embolism, and the initiation of a prostaglandin infusion for ductus-dependent cardiac lesions. There is often a “last-drop” phenomenon associated with some obstrusive lesions, in that small additional amounts of intravascular volume depletion may lead to a rapid deterioration, including cardiac arrest, if the obstructive lesion is not corrected.

Regardless of the etiology of shock, metabolic status should be meticulously maintained (see Table 70-8). Electrolyte levels should be monitored closely and corrected as needed. Hypoglycemia is common and should be promptly treated. Neonates and infants in particular may have profound glucose dysregulation in association with shock. Glucose levels should be checked routinely and treated appropriately, especially early in the course of illness. Hypocalcemia, which may contribute to myocardial dysfunction, should be treated with a goal of normalizing the ionized calcium concentration. There is no evidence that supranormal calcium levels benefit the myocardium, and hypercalcemia may actually be associated with increased myocardial toxicity.

Adrenal function is another important consideration in shock, and hydrocortisone replacement may be beneficial. Up to 50% of critically ill patients may have absolute or relative adrenal insufficiency. Patients at risk for adrenal insufficiency include those with congenital adrenal hypoplasia, abnormalities of the hypothalamic-pituitary axis, and

| Table 70-13 Cardiovascular Drug Treatment of Shock |
|----------------|----------------|----------------|
| **DRUG**      | **EFFECT(S)**                          | **DOsing RANGE** |

Recent therapy with corticosteroids (including patients with asthma, rheumatic diseases, malignancies, and inflammatory bowel disease). These patients are at high risk for adrenal dysfunction and should receive stress doses of hydrocortisone. Steroids may also be considered in patients with shock that is unresponsive to fluid resuscitation and catecholamines. While there may be a subset of pediatric septic shock patients that benefit from treatment with hydrocortisone, currently available pediatric data do not demonstrate an overall survival benefit in patients with shock treated with hydrocortisone. Determination of baseline cortisol levels prior to steroid administration may be beneficial in guiding therapy, although this idea remains controversial.

**Considerations for Continued Therapy**

After the 1st hr of therapy and attempts at early reversal of shock, focus on goal-directed endpoints should continue in an intensive care setting (see Fig. 70-1 and Table 70-8). Clinical endpoints serve as global markers for organ perfusion and oxygenation. Laboratory parameters such as SVO₂ (or ScvO₂), serum lactate concentration, cardiac index, and hemoglobin serve as adjunctive measures of tissue oxygen delivery. Hemoglobin should be maintained at 10 g/dL, SVO₂ (or ScvO₂) >70%, and cardiac index at 3.3-6.0 L/min/m² to optimize oxygen delivery in the acute phase of shock. It is important to note that cardiac index is rarely monitored in the clinical setting owing to the limited use of pulmonary artery catheters and the lack of accurate noninvasive cardiac output monitors for infants and children. Blood lactate levels and calculation of base deficit from arterial blood gas values are very useful markers for the adequacy of oxygen delivery. These traditional markers are all indicators of global oxygen utilization and delivery, and there is increasing interest in measures of local tissue oxygenation including near infra-red spectroscopy of the cerebrum, flank, or abdomen.

Respiratory support should be used as clinically appropriate. When shock leads to ARDS requiring mechanical ventilation, lung-protective strategies to keep plateau pressure below 30 cm H₂O and maintain tidal volume at 6 mL/kg have been shown to improve mortality in adult patients (see Chapter 71). These data are extrapolated to pediatric patients because of the lack of definitive pediatric studies in this area. Additionally, after the initial shock state has been reversed, data demonstrate that judicious fluid administration, renal replacement therapy, and fluid removal may also be useful in children with anuria or oliguria and fluid overload (see Chapter 535). Other interventions include correction of coagulopathy with fresh frozen plasma or cryoprecipitate and platelet transfusions as necessary, especially in the presence of active bleeding.

If shock remains refractory despite maximal therapeutic interventions, mechanical support with **extracorporeal membrane oxygenation** or a **ventricular assist device** may be indicated. Extracorporeal membrane oxygenation may be lifesaving in cases of refractory shock regardless of underlying etiology. Similarly, a ventricular assist device may be indicated for refractory cardiogenic shock in the setting of cardiomyopathy or recent cardiac surgery. Systemic anticoagulation, which is required while patients are receiving mechanical support, may be difficult, given the significant coagulopathy often encountered in refractory shock, especially when the underlying etiology is sepsis. Mechanical support in refractory shock poses substantial risks but can improve survival in specific populations of patients.

**PROGNOSIS**

In septic shock, mortality rates are as low as 3% in previously healthy children and 6-9% in children with chronic illness (compared with 25-30% in adults). With early recognition and therapy, the mortality rate for pediatric shock continues to improve, but shock and MODS remain one of the leading causes of death in infants and children. The risk of death involves a complex interaction of factors, including the underlying etiology, presence of chronic illness, host immune response, and timing of recognition and therapy.

Bibliography

The term respiratory distress is often used to indicate signs and symptoms of abnormal respiratory pattern. A child with nasal flaring, tachypnea, chest wall retractions, stridor, grunting, dyspnea, and wheezing is often judged as having respiratory distress. The magnitude of these findings is used to judge the clinical severity of respiratory distress. Although nasal flaring is a nonspecific sign, the other signs are useful in localizing the site of pathology (see Chapters 373 and 374). Respiratory failure is defined as inability of the lungs to provide sufficient oxygen (hypoxic respiratory failure) or remove carbon dioxide (ventilatory failure) to meet metabolic demands. Whereas respiratory
distress is a clinical impression, the diagnosis of respiratory failure indicates inadequacy of oxygenation or ventilation, or both. Respiratory distress can occur in patients without respiratory disease, and respiratory failure can occur in patients without respiratory distress.

**RESPIRATORY DISTRESS**

A careful physical examination must be performed when managing a child in respiratory distress. Nasal flaring is an extremely important sign of distress, especially in infants. It is indicative of discomfort, pain, fatigue, or breathing difficulty. The state of responsiveness is another crucial sign. Lethargy, disinterest in surroundings, and poor cry are suggestive of exhaustion, hypercarbia, and impending respiratory failure. Abnormalities of the rate and depth of respirations can occur with both pulmonary and nonpulmonary causes of respiratory distress. In diseases of decreased lung compliance, such as pneumonia and pulmonary edema, respirations are characteristically rapid and shallow (decreased tidal volume). In obstructive airway diseases, such as asthma and laryngotracheitis, respirations are deep (increased tidal volume) but less rapid. Rapid and deep respirations without other respiratory signs should alert the physician to the possibility of non-respiratory causes of respiratory distress, such as response to metabolic acidosis (diabetic ketoacidosis, renal tubular acidosis) or stimulation of the respiratory center (encephalitis, ingestion of central nervous system [CNS] stimulants). Chest wall, suprasternal, and subcostal retractions are manifestations of increased inspiratory effort, weak chest wall, or both. Inspiratory stridor indicates airway obstruction above the thoracic inlet, whereas expiratory wheezing results from airway obstruction below the thoracic inlet. Grunting is most commonly heard in diseases with decreased functional residual capacity (e.g., pneumonia, pulmonary edema) and peripheral airway obstruction (e.g., bronchiolitis).

**Respiratory Disease Manifesting as Respiratory Distress**

Clinical examination is important in localizing the site of pathology (see Chapter 373). Extrathoracic airway obstruction occurs anywhere above the thoracic inlet. Inspiratory stridor, suprasternal, chest wall, and subcostal retractions, and prolongation of inspiration are hallmarks of extrathoracic airway obstruction. By comparison, features of intrathoracic airway obstruction are prolongation of expiration and expiratory wheezing. Typical manifestations of alveolar interstitial pathology are rapid, shallow respirations, chest wall retractions, and grunting. The site of pathology can be localized and the differential diagnosis established on the basis of the clinical signs and symptoms (Tables 71-1 and 71-2).

**Respiratory Distress without Respiratory Disease**

Although respiratory distress most commonly results from diseases of lungs, airways, and chest wall, pathology in other organ systems can manifest as “respiratory distress” and lead to misdiagnosis and inappropriate management (Table 71-3). Respiratory distress resulting from heart failure or diabetic ketoacidosis may be misdiagnosed as asthma and improperly treated with albuterol, resulting in worsened hemodynamic state or ketoacidosis. Careful history and physical examination provide essential clues in avoiding misdiagnosis.

**Cardiovascular Disease Manifesting as Respiratory Distress**

A child with cardiovascular pathology may present with respiratory distress caused by 2 mechanisms: (1) decreased lung compliance and (2) cardiogenic shock (Table 71-4). Diseases that result in an increased pulmonary arterial blood flow (e.g., left-to-right shunts) or increased pulmonary venous pressure (e.g., left ventricular dysfunction from hypertension or myocarditis, obstructed total anomalous pulmonary...
venous return) cause an increase in pulmonary capillary pressure and transudation of fluid into the pulmonary interstitium and alveoli. The increased pulmonary blood and water content leads to decreased lung compliance and results in rapid shallow respirations.

It is important to recognize that interstitial lung edema can not only manifest as alveolar fluid, but as small airway obstruction as well. Wheezing as a sign of congestive cardiac disease is common in infants and young children and should be recognized. Patients with cardiac lesions that result in a low cardiac output state, such as obstructive lesions of left side of the heart and acquired or congenital cardiomyopathy, often present in a state of shock with decreased tissue perfusion and metabolic acidosis. Such children demonstrate respiratory distress because of stimulation of chemoreceptors by metabolic acidosis and stimulation of baroreceptors by decreased blood pressure. The likelihood of a particular cardiovascular illness manifesting as respiratory distress depends on age at presentation (Table 71-5).

### Neurologic Disease Manifesting as Respiratory Distress

CNS dysfunction can lead to alterations in respiratory patterns. Increased intracranial pressure (ICP) may manifest as respiratory distress. Early rise in ICP results in stimulation of respiratory centers, leading to increases in the rate (tachypnea) and depth (hyperpnea) of respiration. The resultant decrease in PaCO2 and elevation of cerebrospinal fluid pH lead to cerebral vasoconstriction and amelioration of intracranial hypertension. Cerebral hemispheric and midbrain lesions often result in hyperpnea as well as tachypnea. In such situations, blood gas measurements typically show respiratory alkalosis without hypoxemia. Pathology affecting the pons and medulla manifests as irregular breathing patterns such as apneustic breathing (prolonged inspiration), Cheyne-Stokes breathing (alternate periods of rapid and slow breathing), and irregular, ineffective breathing or apnea. Level of consciousness is most often impaired when abnormal breathing pattern from a brainstem disorder is present. Along with respiratory changes, other manifestations of CNS dysfunction and increased ICP may be present, such as focal neurologic signs, pupillary changes, hypertension, and bradycardia (see Chapter 63). Occasionally, severe CNS dysfunction can result in neurogenic pulmonary edema and respiratory distress, which may be a result of excessive sympathetic discharge resulting in increased pulmonary venous hydrostatic pressure as well as increased pulmonary capillary pressure.

permeability. Central neurogenic hyperventilation is characteristically observed in CNS involvement by illnesses such as urea cycle defects and encephalitis. Bradycardia and apnea may be caused by CNS-depressant medications, poisoning, prolonged hypoxia, trauma, or infection (see Table 71-2).

**Toxic-Metabolic States Manifesting as Respiratory Distress**

Direct stimulation of respiratory centers resulting in respiratory alkalosis is encountered in certain intoxications, such as those involving salicylates and theophylline. Similarly, intoxication with general CNS stimulants, such as cocaine and amphetamines may manifest as increased respirations. Presence of endogenous and exogenous CNS stimulants, such as organic acidemias, ingestion of methanol and ethylene glycol, and late stages of salicylism, cause metabolic acidosis and compensatory hyperventilation, which can manifest as respiratory distress. Blood gas measurements show decreased pH and compensatory hypocarbia with normal oxygenation. Metabolic disorders causing hyperammonemia, on the other hand, cause respiratory alkalosis (decreased PaCO₂ with increased pH) because ammonia is a stimulant of respiratory centers.

**Other Nonpulmonary Entities Manifesting as Respiratory Distress**

Sepsis and septic shock may manifest as respiratory distress by causing acute respiratory distress syndrome (ARDS), hypovolemic stimulation of baroreceptors, stimulation of respiratory centers by cytokines, and lactic acidosis. Other indirect causes of lung injury include systemic inflammatory conditions, trauma, transfusion-related acute lung injury, and pancreatitis. Similarly, renal disease may manifest as respiratory distress by causing metabolic acidosis (e.g., renal tubular acidosis or renal failure) or hypertensive left ventricular failure and fluid overload.

### RESPIRATORY FAILURE

Respiratory failure occurs when oxygenation and ventilation are insufficient to meet the metabolic demands of the body. Respiratory failure may result from an abnormality in (1) lung and airways, (2) chest wall and muscles of respiration, or (3) central and peripheral chemoreceptors. Clinical manifestations depend largely on the site of pathology (Table 71-6). Although respiratory failure is traditionally defined as respiratory dysfunction resulting in PaO₂ <60 mm Hg with breathing of room air and PaCO₂ >50 torr resulting in acidosis, the patient's general state, respiratory effort, and potential for impending exhaustion are more important indicators than blood gas values.

Acute lung injury due to pneumonia, sepsis, aspiration, drowning, embolism, trauma, smoke inhalation, or drug overdose may lead to the ARDS (Tables 71-7 and 71-8; Fig. 71-1).

### Pathophysiology of Respiratory Failure

Respiratory failure can be classified into (1) hypoxic respiratory failure (failure of oxygenation) and (2) hypercarbic respiratory failure (failure of ventilation). Systemic venous (pulmonary arterial) blood is arterialized after equilibration with alveolar gas in the pulmonary capillaries and is carried back to the heart by pulmonary veins. The arterial gas is influenced by the composition of inspired gas, and the effectiveness of alveolar ventilation, pulmonary capillary perfusion, and diffusion capacity of the alveolar capillary membrane. Abnormality at any of these steps can result in respiratory failure. Hypoxic respiratory failure results from intrapulmonary shunting and venous admixture or insufficient diffusion of oxygen from alveoli into pulmonary capillaries. This can be

**New Berlin Definition of ARDS in Infancy and Early Childhood**

*If altitude is higher than 1,000 m, the correction factor should be calculated as follows: [PaO₂/FIO₂ × (barometric pressure/760)].

†This may be delivered noninvasively in the mild acute respiratory distress syndrome group.

CPAP, continuous positive airway pressure; FIO₂, fraction of inspired oxygen; PaO₂, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure.
caused by conditions such as small airway obstruction, increased barrier to diffusion (such as interstitial edema or fibrosis), or in conditions where alveoli are collapsed or filled with fluid (e.g., ARDS, pneumonia, atelectasis, or pulmonary edema). In most cases, hypoxic respiratory failure is associated with a decreased functional residual capacity, and can be managed by recruitment with positive pressure ventilation. Hypercarbic respiratory failure is caused by decreased minute alveolar ventilation (tidal volume multiplied by respiratory rate). This can occur from centrally-mediated disorders of respiratory drive, increased dead space ventilation, or obstructive airway disease. The two entities may coexist as a combined failure of oxygenation and ventilation.

**Ventilation–Perfusion Mismatch, Venous Admixture, Intrapulmonary Shunt**

For exchange of O\(_2\) and CO\(_2\) to occur, alveolar gas must be exposed to blood in pulmonary capillaries. Both ventilation and perfusion are lower in nondependent areas of the lung and higher in dependent areas of the lung. The difference in perfusion (Q) is greater than the difference in ventilation (V). Perfusion in excess of ventilation results in incomplete “arterialization” of systemic venous (pulmonary arterial) blood and is referred to as venous admixture. Perfusion of unventilated areas is referred to as intrapulmonary shunting of systemic venous blood to systemic arterial circulation. Conversely, ventilation that is in excess of perfusion is “wasted”; that is, it does not contribute to gas exchange and is referred to as dead space ventilation. Dead space ventilation results in return of greater amounts of atmospheric gas which has not participated in gas exchange and has negligible CO\(_2\) to the atmosphere during exhalation. The end result is a decrease in mixed expired P\(_{CO_2}\) (P\(_{E_{CO_2}}\)) and an increase in the P\(_{ACO_2}\)-P\(_{E_{CO_2}}\) gradient. The fraction of tidal volume that occupies dead space (V\(_D/\)V\(_T\)) is calculated as follows:

\[ (P_{ACO_2} - P_{E_{CO_2}}) + P_{ACO_2} \]

Normal V\(_D/\)V\(_T\) is around 0.33. V\(_D/\)V\(_T\) increases in states that result in decreased pulmonary perfusion, such as pulmonary hypertension, hypovolemia, and decreased cardiac output. Venous admixture and intrapulmonary shunting predominantly affect oxygenation, resulting in a P\(_{AO_2}\)-P\(_{A_{CO_2}}\) (A-a\(_{CO_2}\)) gradient without elevation in P\(_{ACO_2}\). This is caused by the greater ventilation of perfused areas, which is sufficient to normalize P\(_{ACO_2}\) but not P\(_{AO_2}\) because of their respective dissociation curves (see Chapter 365). The relative straight-line relationship of hemoglobin-CO\(_2\) dissociation allows for averaging of P\(_{CO_2}\) from hyperventilated and hypoventilated areas. Because the association between oxygen tension and hemoglobin saturation plateaus with increasing P\(_{AO_2}\), the decreased hemoglobin-O\(_2\) saturation in poorly ventilated areas cannot be compensated for by well-ventilated areas where hemoglobin-O\(_2\) saturation has already reached near-maximum. This results in decreased arterial oxyhemoglobin saturation (Sa\(_{O_2}\)) and Pa\(_{O_2}\). Elevation of P\(_{ACO_2}\) in such situations is indicative of coincident alveolar hypoventilation. Examples of diseases leading to venous admixture include asthma and aspiration pneumonia, and those of intrapulmonary shunt include lobar pneumonia and ARDS.

**Diffusion**

Even if ventilation and perfusion are matched, gas exchange requires diffusion across the interstitial space between alveoli and pulmonary capillaries. Under normal conditions, there is sufficient time for the pulmonary capillary blood to equilibrate with alveolar gas across the interstitial space. When the interstitial space is filled with inflammatory cells or fluid, diffusion is impaired. Because the diffusion capacity of CO\(_2\) is 20 times greater than that of O\(_2\), diffusion defects manifest as hypoxemia rather than hypercarbia. Even with the administration of 100% oxygen, Pa\(_{O_2}\) increases to around 660 torr from 100 torr at sea level, and the concentration gradient for diffusion of O\(_2\) is increased by only 6.6 times. Therefore, with diffusion defects, lethal hypoxemia will set in before clinically significant CO\(_2\) retention results. In fact, in such situations P\(_{CO_2}\) is often decreased because of the hyperventilation that accompanies hypoxemia. Presence of hypercarbia in diseases that impair diffusion is indicative of alveolar hypoventilation from coexisting airway obstruction, exhaustion, or CNS depression. Examples of disease that impair diffusion are interstitial pneumonia, ARDS, scleroderma, and pulmonary lymphangiectasia.

**MONITORING A CHILD IN RESPIRATORY DISTRESS AND RESPIRATORY FAILURE**

**Clinical Examination**

It cannot be overemphasized that clinical observation is the most important component of monitoring. The presence and magnitude of abnormal clinical findings, their progression with time, and their temporal relation to therapeutic interventions serve as guides to diagnosis and management (see Chapter 373). As much as possible, the child with respiratory distress or failure should be observed in the position of greatest comfort and in the least threatening environment.

**Pulse oximetry** is the most commonly utilized technique to monitor oxygenation. Noninvasive and safe, it is the standard of care in bedside monitoring of children during transport, procedural sedation, surgery, and critical illness. It indirectly measures arterial hemoglobin-O\(_2\) saturation by differentiating oxyhemoglobin from deoxygenated hemoglobin using their respective light absorption at wavelengths of 660 nm (red) and 940 nm (infrared). A pulsatile circulation is required to enable detection of oxygenated blood entering the capillary bed. Percentage of oxyhemoglobin is reported as Sa\(_{O_2}\); however, the correct description is oxyhemoglobin saturation as measured by pulse oximetry (Sp\(_o_2\)). This is because Sp\(_o_2\) may not reflect Sa\(_{O_2}\) in certain situations. It is important to be familiar with the hemoglobin-O\(_2\) dissociation curve (see Chapter 373) in order to estimate Pa\(_{O_2}\) at a given oxyhemoglobin saturation. Because of the shape of the hemoglobin-O\(_2\) dissociation curve, changes in Pa\(_{O_2}\) above 70 torr are not readily identified by pulse oximetry. Also, at the same Pa\(_{O_2}\) level, there may be a significant change in Sp\(_o_2\) at a different blood pH value. In most situations, an Sp\(_o_2\) value greater than 95% is a reasonable goal, especially in emergency situations. There are exceptions, such as in patients with single ventricle cardiac lesions, in whom the pulmonary and systemic circulations are receiving blood flow from the same ventricle (e.g., after Norwood procedure for hypoplastic left heart syndrome), or with large left-to-right shunts (e.g., ventricular septal defect and patent ductus arteriosus). In these types of pathophysiologic situations, a lower Sp\(_o_2\)
is desired to avoid excessive blood flow to the lungs and pulmonary edema from the pulmonary vasodilatory effects of oxygen, and, in the patient with a single ventricle, diverting blood flow away from the systemic circulation. Because most commercially available pulse oximeters recognize all types of hemoglobin as either oxyhemoglobin or deoxygenated hemoglobin, they provide inaccurate information in the presence of carboxyhemoglobin and methemoglobin. In carbon monoxide poisoning, carboxyhemoglobin absorbs light in the same (red) wavelength as oxyhemoglobin, leading to overestimation of oxygen saturation. Methemoglobin absorbs light in both the oxygenated and deoxygenated wavelengths, which can cause either an overestimation or underestimation of oxygen saturation. Data suggests that increasing methemoglobin concentrations tend to drive $\text{SpO}_2$ toward 85%, no matter the actual percent of oxyhemoglobin. At lower methemoglobin levels, the pulse oximetry reading is falsely low, whereas high levels lead to a falsely high pulse oximetry reading. Newer pulse oximeters may have the ability to distinguish dыхемоглобинемias and to prevent false readings, but these are not currently in widespread use. It should be recognized that dangerous levels of hypercarbia may exist in patients with ventilatory failure, who have satisfactory $\text{SpO}_2$ if they are receiving supplemental oxygen. Pulse oximetry should not be the only monitoring method in patients with primary ventilatory failure, such as neuromuscular weakness and CNS depression. It is also unreliable in patients with poor perfusion and poor pulsatile flow to the extremities. Despite these limitations, pulse oximetry is a noninvasive, easily applicable, and effective means of evaluating the percentage of oxyhemoglobin in most patients.

Capnography (end-tidal CO$_2$ measurement) is helpful in determining the effectiveness of ventilation and pulmonary circulation. This method is especially useful for monitoring the level of ventilation in intubated patients. Diseases resulting in increased dead space or decreased pulmonary blood flow lead to decreases in end-tidal CO$_2$ and an overestimation of the adequacy of ventilation.

**Blood Gas Abnormalities in Respiratory Distress and Respiratory Failure**

Arterial blood gas analysis offers valuable assistance in diagnosis, monitoring, and management of a child in respiratory distress and failure. Because of technical difficulties in obtaining an arterial sample in children, a capillary blood gas (CBG) sample is most often obtained in emergency situations. A properly “arterialized” CBG sample obtained by warming the digit and obtaining free flowing blood is acceptable. The blood sample needs to be processed without delay. CBG provides a good estimate of $\text{PaCO}_2$ and arterial pH, but less so for $\text{PaO}_2$. In patients who mainly require monitoring of their ventilation (especially those whose oxygenation is being monitored with pulse oximetry) a venous blood gas sample provides a reliable estimate of arterial pH and $\text{PaCO}_2$ values, provided tissue perfusion is reasonably adequate. Venous $\text{PaCO}_2$ is approximtely 6 torr higher and pH approximately 0.03 lower than the arterial values. Venous $\text{PaO}_2$ has a poor correlation with $\text{PaO}_2$. Mixed venous $\text{O}_2$ saturation obtained from a central venous catheter in the right atrium is an excellent marker of the balance between oxygen delivery and oxygen consumption. In patients with a constant arterial $\text{O}_2$ content and $\text{O}_2$ consumption, mixed venous $\text{O}_2$ saturation offers valuable information regarding cardiac output.

Blood gas analysis is important not only for determining the adequacy of oxygenation and ventilation but also for determining site of the respiratory pathology and planning treatment (see Chapter 373). Briefly, in presence of pure alveolar hypoventilation (such as airway obstruction above the carina, decreased $\text{CO}_2$ responsiveness and neuromuscular weakness), the blood gas will show respiratory acidosis with an elevated $\text{Pco}_2$ but a relative sparing of oxygenation. V/Q mismatch (peripheral airway obstruction, bronchopneumonia) will be reflected in increased hypoxemia and variable levels of $\text{Pco}_2$ (low, normal, high) depending on severity of disease. Intrapulmonary right to left shunting and diffusion defects (alveolar-interstitial diseases such as pulmonary edema, ARDS) will be associated with a large A-a$\text{O}_2$ gradient and hypoxemia with relative sparing of $\text{CO}_2$ elimination unless there is coincident fatigue or CNS depression.

**Acid–Base Abnormalities in a Child with Respiratory Distress and Respiratory Failure**

It is crucial to analyze the magnitude and appropriateness of changes in pH, $\text{Pco}_2$ and bicarbonate ($\text{HCO}_3^-$) as they provide useful clues to the underlying pathophysiology and presence of more than one disorder. To do so, it is useful to assume baseline values of pH 7.40, $\text{Pco}_2$ 40 torr, and $\text{HCO}_3^-$ 24 mEq/L. Newborns have lower renal threshold for bicarbonate and therefore have slightly different baseline values of pH 7.38, $\text{Pco}_2$ 35 torr and $\text{HCO}_3^-$ 20 mEq/L.

**Metabolic Acidosis with Respiratory Compensation**

Patients with metabolic acidosis have decreased pH resulting from decreased serum bicarbonate. Chemoreceptor stimulation results in hyperventilation and respiratory compensation which may clinically manifest as respiratory distress. It should be recognized that a normal compensation does not completely correct the pH but rather minimizes a change in pH that would otherwise occur without compensation. The adequacy of respiratory compensation is judged by the extent of the decline in $\text{PaCO}_2$ in response to the decline in $\text{HCO}_3^-$ or pH. A normal compensation for metabolic acidosis results in a fall in $\text{Pco}_2$ by 1.2 torr for every 1 mEq/L fall in $\text{HCO}_3^-$. The most commonly used method to analyze the adequacy of respiratory compensation is the Winter’s formula: $\text{PaCO}_2 = (\text{HCO}_3^- × 1.5) + 8 ± 2$. A quick method is to look at the last 2 digits of pH (provided it is not below 7.10) which should be within 2 torr of $\text{Pco}_2$. For example, pH 7.27, $\text{Pco}_2$ 26 torr, and bicarbonate 12 mEq/L represents metabolic acidosis with a normal respiratory compensation response. On the other hand, pH 7.15, $\text{Pco}_2$ 30 torr, and $\text{HCO}_3^-$ 10 mEq/L constitutes metabolic acidosis with inadequate respiratory compensation. The reasons for inadequate compensation include decreased $\text{CO}_2$ responsiveness (e.g. narcotic poisoning, cerebral edema), abnormalities of lungs and airways, or neuromuscular weakness. A decrease in $\text{PaCO}_2$ that is greater than what could be expected as a normal compensatory response to metabolic acidosis is indicative of a mixed disorder. For example, a pH 7.20, $\text{Pco}_2$ 15 torr, and $\text{HCO}_3^-$ 7.5 mEq/L represents metabolic acidosis with a concomitant respiratory alkalosis because the decline in $\text{Pco}_2$ is greater than what can be expected as normal compensation. Combination of metabolic acidosis and respiratory alkalosis is often encountered in serious conditions such as cardiogenic shock (anxiety, stimulation of baroreceptors), sepsis, or toxic-metabolic states (salicylates, organic academia).

**Respiratory Acidosis with Metabolic Compensation**

Patients with respiratory acidosis have decreased pH as a result of elevated $\text{PaCO}_2$. An acute increase in $\text{Pco}_2$ of 10 torr results in a decrease in pH by 0.08. Thus, a child with severe status asthmaticus and a $\text{Pco}_2$ of 60 torr will have blood pH of around 7.24. Chronically elevated (greater than 3–5 days) $\text{Pco}_2$ is accompanied by renal compensation and increase in serum bicarbonate limiting the fall in pH to 0.03 for every 10 torr rise in $\text{Pco}_2$. Thus an infant with bronchopulmonary dysplasia who has a basal $\text{PaCO}_2$ of 60 torr will have blood pH around 7.34. These findings are helpful in distinguishing acute vs. chronic changes in $\text{PaCO}_2$. Also, for a given level of $\text{CO}_2$ accumulation, a decrease in pH that is greater than expected is indicative of concomitant metabolic acidosis and a decline in pH that is less than expected is due to accompanying metabolic alkalosis.

**Assessment of Oxygenation and Ventilation Deficits**

For standardizing management, following clinical progress, and determining prognosis for patients with defects in oxygenation or ventilation, various indicators have been proposed. Each one has its strengths and limitations:

- **A-a$\text{O}_2$ gradient**: Calculated by subtracting arterial $\text{Pao}_2$ from alveolar $\text{P}_a$ ($\text{P}_a = \text{Paco}_2 + \text{Pao}_2$). For the comparison to be valid, it must be at the same $\text{FiO}_2$.

- **$\text{Pao}_2$/$\text{FiO}_2$ ratio**: is calculated by dividing arterial $\text{Pao}_2$ by $\text{FiO}_2$. In hypoxic respiratory failure, a $\text{Pao}_2$/$\text{FiO}_2$ value <300 is consistent with acute lung injury, and a value <200 is consistent with ARDS.
Although the intent is to measure V/Q mismatch, intrapulmonary shunt, and diffusion defect, the status of alveolar hypoventilation could have a significant impact on PaO₂/Fio₂. PaO₂/PaO₂ is determined by dividing arterial PaO₂ by alveolar PaO₂. The level of alveolar ventilation is accounted for in the calculation of PaO₂. Therefore, PaO₂/PaO₂ is more indicative of V/Q mismatch and alveolar capillary integrity.

**Oxygenation index (OI)** is aimed at standardizing oxygenation to the level of therapeutic interventions such as mean airway pressure (MAP) and Fio₂, which are directed toward improving oxygenation. None of the previously mentioned indicators of oxygenation account for the degree of positive pressure respiratory support. OI is calculated as follows:

\[ OI = \left( \frac{MAP \times %O_2 \text{ inspired}}{Paco_2} \right) \]

The limitation of OI is that level of ventilation is not accounted for in the assessment.

**Ventilation index (VI)** is aimed at standardizing alveolar ventilation to the level of therapeutic interventions (such as peak inspiratory pressure [PIP] and ventilator rate) directed toward lowering Paco₂. VI is calculated as follows:

\[ VI = \left( \frac{\text{Ventilator Rate} \times (\text{PIP} - \text{PEEP}) \times \text{Paco}_2}{1000} \right) \]

### MANAGEMENT

The goal of management for respiratory distress and respiratory failure is to ensure a patent airway and provide necessary support for adequate oxygenation of the blood and removal of CO₂. Compared with hypercapnia, hypoxemia is a life-threatening condition; therefore, initial therapy for respiratory failure should be aimed at ensuring adequate oxygenation.

### Oxygen Administration

Supplemental oxygen administration is the least invasive and most easily tolerated therapy for hypoxic respiratory failure. **Nasal cannula** oxygen provides low levels of oxygen supplementation and is easy to administer. Oxygen is humidified in a bubble humidifier and delivered via nasal prongs inserted into the nares. In children, a flow rate <5 L/min is most often used because of increasing nasal irritation with higher rates. A common formula for an estimation of the Fio₂ during use of a nasal cannula in older children and adults is as follows:

\[ \text{Fio}_2 \% \text{O}_2 \text{ delivered} = 21\% + \left( \frac{\text{nasal cannula flow} \text{ (L/min)} \times 3}{} \right) \]

The typical Fio₂ value using this method is between 23% and 40%, although the Fio₂ varies according to the size of the child, the respiratory rate, and the volume of air moved with each breath. In a young child, because typical nasal cannula flows are a greater percentage of total minute ventilation, significantly higher Fio₂ may be provided. Alternately, a **simple mask** may be employed, which consists of a mask with open side ports and a valveless oxygen source. Variable amounts of room air are entrained through the ports and around the side of the mask, depending on the fit, size, and minute volume of the child. Oxygen flow rates vary from 5-10 L/min, yielding typical Fio₂ values between 0.30 and 0.65. If more precise delivery of oxygen is desired, other mask devices should be used.

A **Venturi mask** delivers preset fractions of oxygen through a mask and reservoir system by entraining precise amounts of room air into the reservoir with high-flow oxygen. The amount of room air entrainment and subsequent Fio₂ are determined by the adapter at the end of each mask reservoir. The adapter can be chosen to provide between 30% and 50% oxygen concentrations. Oxygen flow rates of 5-10 L/min are recommended to achieve desired Fio₂ and to prevent rebreathing. **Partial rebreather and nonrebreather** masks use a reservoir bag attached to a mask to provide higher fractions of oxygen. Partial rebreather masks have 2 open exhalation ports and contain a valveless oxygen reservoir bag. Some exhaled gas can mix with reservoir gas during exhalation, although most exits the mask via the exhalation ports. Through these ports, room air is also entrained during inspiration. A partial rebreather mask can provide up to 0.6 Fio₂ as long as oxygen flow is adequate to keep the bag from collapsing (typically 10-15 L/min). As with nasal cannulas, smaller children with smaller tidal volumes entrain less room air, and their Fio₂ values will be higher. Nonrebreather masks include 2 one-way valves, 1 between the oxygen reservoir bag and the mask and 1 on 1 of the 2 exhalation ports. This arrangement minimizes mixing of exhaled and fresh gas and entrainment of room air during inspiration. The second exhalation port has no valve, a safeguard to allow some room air to enter the mask in the event of disconnection from the oxygen source. A nonrebreather mask can be useful in conjunction with an oxygen blender allows delivery of fractions of oxygen between 0.50 and 0.95. When supplemental oxygen alone is inadequate to improve oxygenation, or when ventilation problems coexist, additional therapies may be necessary.

### Airway Adjuncts

Maintenance of a patent airway is a critical step in maintaining adequate oxygenation and ventilation. Artificial pharyngeal airways may be useful in patients with oropharyngeal or nasopharyngeal airway obstruction and in those with neuromuscular weakness in whom native extrathoracic airway resistance contributes to respiratory compromise. An **oropharyngeal airway** is a stiff plastic spacer with grooves along each side that can be placed in the mouth to run from the teeth along the tongue to its base just above the vallecula. The spacer prevents the tongue from opposing the posterior pharynx and occluding the airway. Because the tip sits at the base of the tongue, it is usually not tolerated by patients who are awake or whose gag reflex is strong. The **nasopharyngeal airway**, or nasal trumpet, is a flexible tube that can be inserted into the nose to run from the nasal opening along the top of the hard and soft palate with the tip ending in the hypopharynx. It is useful in bypassing obstruction from enlarged adenoids or from contact of the soft palate with the posterior nasopharynx. Because it is inserted past the adenoids, a nasopharyngeal airway should be used with caution in patients with bleeding tendencies.

### Inhaled Gases

**Helium-oxygen mixture (heliox)** is useful in overcoming airway obstruction and improving ventilation. Helium is much less dense and slightly more viscous than nitrogen. When substituted for nitrogen, helium helps maintain laminar flow across an obstructed airway, decreases airway resistance, and improves ventilation. It is especially helpful in diseases of large airway obstruction in which turbulent airflow is more common, such as acute laryngotracheobronchitis, subglottic stenosis, and vascular ring. It is also used in patients with severe status asthmaticus. To be effective, helium should be administered in concentrations of at least 60%, so associated hypoxemia may limit its use in patients requiring more than 40% oxygen. **Nitric oxide (NO)** is a powerful inhaled pulmonary vasodilator. Its use may improve pulmonary blood flow and V/Q mismatch in patients with diseases that elevate pulmonary vascular resistance, such as persistent pulmonary hypertension of the newborn, primary pulmonary hypertension, and secondary pulmonary hypertension as a result of chronic excess pulmonary blood flow (e.g., ventriculopectal defect) or collagen vascular diseases. NO is administered in doses ranging from 5-20 parts per million. Although administration of NO to unintubated patients is possible, it is usually administered to patients receiving mechanical ventilation through endotracheal tubes, because of the need for precision in NO dosing.

### Positive-Pressure Respiratory Support

Noninvasive positive-pressure respiratory support is useful in treating both hypoxemic and hypoventilatory respiratory failure. Positive airway pressure helps aerate partially atelectatic or filled alveoli, prevent alveolar collapse at end exhalation, and increase functional residual capacity (FRC). This improves pulmonary compliance and hypoxemia and decreases intrapulmonary shunt. In addition, positive pressure ventilation is useful in preventing collapse of extrathoracic airways by maintaining positive airway pressure during inspiration. Improving compliance and overcoming airway resistance also improves tidal volume and, therefore, ventilation. **A high-flow nasal cannula** delivers
gas flow at 4-16 L/min, providing significant continuous positive airway pressure (CPAP). The amount of CPAP provided is not quantifiable and varies with each patient, depending on the percentage of total inspiratory flow that is delivered from the cannula, airway anatomy, and degree of mouth breathing. In small children, the relative amount of CPAP for a given flow is usually greater than in older children, and may provide significant positive pressure. The FiO₂ can be adjusted by provision of gas flow through an oxygen blender. Another benefit of a high-flow nasal cannula system is the washout of CO₂ from the nasal pharynx, which decreases rebreathing of CO₂ and dead space ventilation. For delivery of high-flow air or oxygen, adequate humidification is essential and is achieved with use of a separate heated humidification chamber. CPAP can also be provided through snugly fitting nasal prongs or a tight-fitting facial mask attached to a ventilator or other positive-pressure device. Noninvasive CPAP is most useful in diseases of mildly decreased lung compliance and low FRC, such as atelectasis and pneumonia. Diseases of extrathoracic airway obstruction in which extrathoracic negative airway pressures during inspiration lead to airway narrowing (e.g., laryngotracheitis, obstructive sleep apnea, postextubation airway edema) may also benefit from CPAP. Potential risks include nasal irritation, hyperinflation from excessive CPAP in smaller patients, and abdominal distention from swallowed air.

**Bilevel positive airway pressure (BiPAP)** machines provide positive airway pressure during exhalation and additional positive pressure during inspiration. A BiPAP device allows one to set an expiratory positive airway pressure and an inspiratory positive airway pressure. The additional positive pressure during inspiration helps augment tidal volume and improve alveolar ventilation in low compliance and obstructive lung disease. The inspiratory and expiratory pressures can be adjusted independently to suit individual needs and comfort. Because of the additional support during inspiration, patients with neuromuscular weakness in particular tend to benefit from BiPAP support. BiPAP may also be helpful in diseases of intrathoracic airway obstruction. During exhalation, expiratory positive airway pressure can decrease the effects of airway closure by raising intraluminal pressure and ameliorating intrathoracic airway collapse. During inspiration, inspiratory positive airway pressure can unload inspiratory muscles, and decrease work of breathing (Fig. 71-2).

### Endotracheal Intubation and Mechanical Ventilation

When hypoxemia or significant hypoventilation persists despite the interventions already described, tracheal intubation and mechanical ventilation are indicated. Additional indications for intubation include maintaining airway patency in patients who have the potential for airway compromise, such as those with actual or potential neurolologic deterioration, and in patients with hemodynamic instability. Proper monitoring is essential to ensuring a safe and successful tracheal intubation. Pulse oximetry, heart rate, and blood pressure monitoring are mandatory and should be forgone only in situations calling for emergency intubation. All necessary equipment, including bag-mask ventilation device, laryngoscope, tracheal tube with stylet, and suction equipment, must be available and working properly prior to initiation of intubation. The proper internal diameter (ID) for the tracheal tube can be estimated using the following formula:

\[
\text{ID} = (\text{Age [yr]}/4) + 4
\]

Table 71-9 provides average values for age, size, and depth of insertion for tracheal tubes. Preoxygenation of the patient with high fractions of inspired oxygen is essential and will allow maximum procedure time prior to the onset of hypoxemia.

Although intubation can be accomplished without sedation and pharmacologic paralysis in selected patients, the physiologic benefits of these measures to the patient as well as to the facilitation of the intubation usually far outweigh the risks; sedation and paralysis should be considered standard unless contraindicated. Administration of a sedative and analgesic followed by a paralytic agent is a common pharmacologic regimen for facilitating intubation. The particular type and dose of each agent often depends on the underlying disease and clinician preference. Table 71-10 lists commonly used agents. An alternative to this pharmacologic approach, especially when intubation is urgent or the patient is suspected of having a full stomach, increasing the risk of aspiration, is rapid sequence intubation (see Chapter 67).

Once adequate sedation and/or paralysis have been achieved, ventilation should be assisted with a bag-mask device. After optimal

---

**Figure 71-2** Work of breathing (WOB) in status asthmaticus with and without noninvasive positive pressure ventilation. In the expiratory limb of the respiratory cycle, the equal pressure point is displaced distally, causing airways to begin to close at a higher lung volume (increased closing capacity), leading to dynamic hyperinflation, and autopositive end-expiratory pressure (auto-PEEP) (**A**). Application of expiratory positive airway pressure stents the airways, reducing intrathoracic airway collapse, dynamic hyperinflation, auto-PEEP (**B**), and WOB. In the inspiratory limb, the patient needs to generate less negative pressure to initiate inspiration because of lower autopermissive end-expiratory pressure. Inspiratory muscles are further unloaded by inspiratory positive airway pressure (IPAP) throughout inspiration for the given tidal volume. Both expiratory and inspiratory WOB are thus reduced by application of noninvasive positive pressure ventilation. (From Samaik AA, Samaik AP: Noninvasive ventilation in pediatric status asthmaticus: Sound physiologic rationale but is it really safe, effective, and cost-efficient? Pediatr Crit Care Med 13:484–485, 2012.)
preoxygenation, intubation can be performed. The clinician uses his/ her dominant hand to open the patient’s mouth and inserts the laryngoscope blade gently along the tongue to its base. The airway opening can be visualized by applying lift up and away from the clinician, along the axis of the laryngoscope handle. If a straight (Miller) laryngoscope blade is used, the epiglottis is lifted anteriorly by the tip of the blade to visualize the glottis. If a curved (Macintosh) blade is used, the tip should be advanced into the vallecula and then lifted to visualize the glottis. Secretions often obscure visualizations at this step and should be suctioned clear. Once clear visualization of the vocal cords is accomplished, the tube can be placed through the cords. Rapid confirmation of tube placement is essential and should be assessed by all of the following steps as possible: Auscultation of both lung fields as well as the epiglottis for equal breath sounds and good air movement and evaluation of the abdomen for increasing distention should be performed. Adequate bilateral chest expansion and misting inside the tracheal tube with each breath are suggestive of proper tube placement. An increasing heart rate, if heart rate has decreased during the attempt, and a rising or normal pulse oximetry reading are suggestive of successful tube placement. Preoxygenation may significantly delay a drop in SpO2 with improper tube placement, leading to a significant delay in its recognition. Confirmation of exhaled CO₂ is mandatory. It can be accomplished with use of a disposable colorimetric CO₂ detector or with capnography. In situations of very low pulmonary perfusion, such as cardiac arrest, exhaled CO₂ may not be detected. A chest radiograph should also be obtained to confirm proper placement of the tracheal tube, which should lie roughly halfway between the glottis and the carina (see Chapter 62).

**Transient Manual Ventilation in the Immediate Preintubation and Postintubation Periods**

Establishment of ventilation via bag and mask or bag and tracheal tube is required prior to transport of the patient to a setting of continued critical care. The technique of manual ventilation should take into account the underlying pathology. Ventilation of patients with diseases characterized by low FRC (pneumonia, pulmonary edema, ARDS, etc.) should include the application of positive end-expiratory pressure (PEEP) to prevent alveolar derecruitment. This can be accomplished with use of a PEEP valve on a self-inflating ventilation bag or by careful manipulation of exhaust gas using an anesthesia bag. Such diseases are also characterized by a short time constant and therefore are best managed with relatively small tidal volumes and high ventilation rates.

Diseases characterized by airway obstruction have prolonged time constants and are therefore best managed with relatively slow rates and high tidal volumes.

71.1 Mechanical Ventilation

Ashok P. Sarnaik and Christopher Mastropietro

The decision to institute mechanical ventilation is based mainly on the need to assist lung function; supporting left ventricular performance and treating intracranial hypertension are additional indications. Although there are no absolute criteria for derangement of gas exchange, Pao₂ < 60 torr while breathing > 60% oxygen, Paco₂ > 60 torr, and pH < 7.25 are often reasons to initiate mechanical ventilation. Clinical impressions of fatigue and impending exhaustion are also indications for ventilatory support even in the presence of adequate gas exchange. Positive-pressure ventilation is a powerful means of decreasing left ventricular afterload, and it is used for this purpose in patients with cardiogenic shock resulting from left ventricular dysfunction. Mechanical ventilation is also used in patients whose respirations are unreliable (e.g., unconscious patients, those with neuromuscular dysfunction) and when deliberate hyperventilation is desired, such as in patients with intracranial hypertension.

Mechanical ventilation neither is intended to normalize gas exchange nor is a form of cure. The goals are to maintain sufficient oxygenation and ventilation to ensure tissue viability until the disease process has resolved and to minimize the inevitable complications of the therapeutic intervention itself. Pao₂, Paco₂, and pH levels are maintained in ranges that provide a safe environment for the patient while protecting the lungs from damage due to oxygen toxicity, pressure (barotrauma), tidal volume overdistention (volutrauma), atelectrauma, and cytokine release (biotrauma) (Figs. 71-3 and 71-4).

**Basic Concepts of Ventilator Management**

**Equation of Motion**

A pressure gradient is required for air to move from one place to another (Fig. 71-5). During natural spontaneous ventilation, inspiration results from generation of negative intrapleural pressure from

Chapter 71: Respiratory Distress and Failure

1. Pressure gradient is required to move air from one place to another.
2. Movement of air is opposed by flow-resistive and elastic properties of the system.

\[
\text{Pressure gradient} = \frac{\Delta \text{volume}}{\text{compliance}} + \left( \text{Flow} \times \text{resistance} \right)
\]

Elastic properties

Flow-resistive properties

contraction of the diaphragm and intercostal muscles, drawing air from the atmosphere across the airways into the alveoli. During mechanical ventilation, inspiration results from positive pressure created by compressed gases through the ventilator, which pushes air across the airways into alveoli. In both spontaneous and mechanical ventilation, exhalation results from alveolar pressure generated by the elastic recoil of the lung and the chest wall. Pressure necessary to move a given amount of air into the lung is determined by 2 factors: lung and chest wall elastance, and airway resistance. Figure 71-5 describes the relationship among pressure gradient, compliance, and resistance. Elastance—defined as the change in pressure (ΔP) divided by the change in volume (ΔV)—refers to the property of a substance to oppose deformation. It is opposite of compliance (ΔV + ΔP), the property of a substance to allow distention or lengthening when subjected to pressure. Compliance (C) is therefore expressed as 1/elastance.

The pressure needed to overcome tissue elastance is measured in conditions in which there is no flow (at end-inspiration and end-expiration) and is therefore a reflection of static conditions in the lung. It is influenced by tidal volume and compliance (P = ΔV + C). It is increased with high tidal volume and low compliance. This pressure gradient is used to calculate the static compliance of the respiratory system (C_{stat}).

Resistance (R) refers to the opposition to generation of flow. It is measured as the amount of pressure needed to generate a unit of flow (ΔP + ΔF). Pressure needed to overcome airway resistance is calculated as flow multiplied by resistance. Because this pressure is needed only when the flow is occurring through the airways, it is referred to as the dynamic component. Pressure to overcome flow-resistive properties is measured when there is maximum flow and is therefore under dynamic conditions. It is increased in conditions with greater airway resistance and flow rate. Flow rate depends on the time allowed for inspiration and expiration. At higher respiratory rates, there is less time available for each inspiration and expiration, necessitating higher flows; therefore higher pressure is required to overcome flow-resistive properties. The pressure gradient necessary to move air from one place to another is the sum of pressure needed to overcome the elastic and flow-resistive properties of the lung. This pressure gradient is taken into
account to calculate the dynamic compliance of the respiratory system (Cdyn). The difference in change in pressure between static conditions and dynamic conditions is attributable to airway resistance.

**Functional Residual Capacity**
Also see Chapter 373.
During inspiration, oxygen-enriched gas enters alveoli. During exhalation, oxygen continues to be removed by the pulmonary capillary circulation. FRC is the volume of gas left in the alveoli at the end of expiration. It is the only source of gas available for gas exchange during exhalation. In diseases with decreased FRC (e.g., ARDS, pulmonary edema), alveolar oxygen concentration declines sharply throughout expiration, resulting in hypoxemia. Two ventilator strategies commonly employed to improve oxygenation in such situations are the application of PEEP and increasing the inspiratory time (Ti) (Fig. 71-6). PEEP increases FRC, whereas a longer Ti allows longer exposure of pulmonary capillary blood to a higher concentration of O2 during inspiration.

**Time Constant**
At the beginning of inspiration, the atmospheric pressure is higher than the pressure in the alveoli, resulting in movement of air into the alveoli. During mechanical ventilation, the ventilator circuit serves as the patient's atmosphere. As alveoli expand with air, the alveolar pressure rise throughout inspiration until it equilibrates with the ventilator pressure, at which time airflow ceases. Expiration starts when the ventilator pressure falls below the alveolar pressure. Alveolar pressure decreases throughout expiration until it reaches the ventilator pressure, at which time no further egress of air from the alveoli occurs. If inspiration or expiration is terminated before pressure equilibration between alveoli and the ventilator is allowed to occur, alveolar expansion during inspiration or alveolar emptying during expiration is incomplete. Incomplete inspiration results in delivery of decreased tidal volume, whereas incomplete expiration is associated with air trapping and the presence of residual PEEP in the alveoli that is greater than the ventilator pressure, referred to as auto-PEEP. Some time is required for pressure equilibration to occur between alveoli and the atmosphere, which is reflected in the time constant (TC). It takes 3 TCs for 95%, and 5 TCs for 99%, of pressure equilibration to occur. The TC depends on compliance and resistance, and their relationship is depicted in Figure 71-7.

Diseases with decreased compliance (increased elastance) are characterized by high elastic recoil pressure, which results in more rapid equilibration of alveolar and ventilator pressures, thereby decreasing TC. Diseases with increased airway resistance are associated with slower flow rates, require longer time for movement of air from one place to another, and therefore have increased TC. Airways expand during inspiration and narrow during expiration (see Chapter 373). Therefore, expiratory time constant (TCe) is longer than inspiratory time constant (TCi). In intrathoracic airway obstruction (asthma, bronchiolitis, aspiration syndromes), airway narrowing is much more pronounced during expiration. Therefore, although both TCe and TCi are prolonged in such diseases, TCi is much more prolonged than TCe. Patients with such diseases therefore are best ventilated with slower rates, higher tidal volume, and longer expiratory time than inspiratory time. In diseases characterized by decreased compliance, both TCe and TCi are short; however, the TCe is closer to TCi than in normal lungs because of the stiffer alveoli recoil with greater force. Patients with these diseases are best ventilated with small Vt to prevent ventilator-induced lung injury and with a relatively longer inspiratory time in each breath to improve oxygenation.

**Critical Opening Pressure**
Collapsed or atelectatic alveoli require a considerable amount of pressure to open. Once open, the alveoli require relatively less pressure for continued expansion. The process of opening atelectatic alveoli is called recruitment. In a normal lung, alveoli remain open at the end of expiration, and therefore the lung requires relatively less pressure to receive its tidal volume. In a disease process in which the alveoli...
collapse at the end of expiration (e.g., ARDS), a substantial amount of pressure is required to open the alveoli during inspiration. This pressure causes ventilator-induced lung injury via 2 mechanisms: (1) barotrauma at the terminal airway–alveolar junction and (2) volutrauma as a result of overdistention of alveoli that are already open (see Figs. 71-3 and 71-4). Although a pulmonary parenchymal disease process is rarely uniform, and each of the millions of alveoli may have its own mechanical characteristics, a composite volume-pressure relationship could be conceptualized for the whole lung (Fig. 71-8).

In these situations, the lower and upper portions of the curve are relatively horizontal, and the middle portion is more vertical. At the beginning of inspiration, atelectatic alveoli are being recruited, requiring high pressure for a relatively small increase in volume. Once they are recruited, further increase in volume requires relatively less pressure. The pressure at which most alveoli are open is called critical opening pressure; this point is also referred to as the lower inflection point (lower P_{FLEX}). After the lower P_{FLEX}, greater volume can be delivered for relatively less pressure until the upper P_{FLEX} is reached, at which the volume-pressure curve again becomes relatively horizontal. The goal of mechanical ventilation in alveolar interstitial pathology is to deliver a tidal volume between the lower and upper inflection points, the so-called safe zone of ventilation. If V_t is delivered with a change in inflation pressure that includes the lower P_{FLEX}, alveoli are likely to open and close during every breath, a process termed tidal recruitment that is injurious to the lung, especially at the terminal airway–alveolar junction. If V_t is delivered with a change of pressure that includes the upper P_{FLEX} overdistention of alveoli is likely to occur, resulting in volutrauma and barotrauma. Keeping tidal ventilation between the upper and lower P_{FLEX} values is accomplished by maintaining a level of PEEP to produce baseline alveolar recruitment and delivering a relatively small (6 mL/kg) V_t. Termed “open lung” strategy, this approach has proved to be beneficial in alveolar interstitial diseases such as ARDS.

**PHASES OF MECHANICAL VENTILATION**

The planning of a ventilatory strategy must consider the four phases of the respiratory cycle separately, taking into account these patient clinical characteristics: (1) initiation of respiration and a variable that is controlled, often referred to as mode; (2) inspiratory phase characteristics, which determine the duration of inspiration and how the pressure or volume is delivered; (3) termination of inspiration, often referred to as cycle; and (4) expiratory phase characteristics. Ideally, mechanical ventilation should not completely take over the work of breathing but, rather, should assist the patient’s own respiratory effort. In the absence of the patient’s effort, respiratory muscle deconditioning may occur, making weaning from mechanical ventilation more difficult.

### Initiation of Inspiration and the Control Variable (Mode)

The initiation of inspiration may be set to occur at a predetermined rate and interval regardless of patient effort, or it could be timed in response to patient effort. Once inspiration is initiated, the ventilator breath either is controlled entirely by the ventilator (control mode) or supports the patient’s inspiratory effort to a predetermined inspiratory volume or pressure target (support mode). Advances in technology allow for greater patient–ventilator synchrony to occur. The ventilator may be set to be “triggered” by the signal it receives as a result of patient effort. This may be in the form of lowering of either pressure (pressure trigger) or airflow (flow trigger) in the ventilator circuit generated by the patient’s inspiratory effort. If no such signal is received because of lack of patient effort, the ventilator delivers a breath at an interval selected by the operator.

### Control Modes - Intermittent Mandatory Ventilation Mode

In intermittent mandatory ventilation (IMV), the inspiration is initiated at a set frequency with a timing mechanism independent of patient effort. In between machine-delivered breaths, the patient can breathe spontaneously from a fresh source of gas. IMV allows for adjustment of ventilator support according to the patient’s needs, making it useful in the weaning process. Lack of synchrony between machine-delivered breaths and patient efforts may result in ineffective ventilation and patient discomfort, especially when IMV is delivered at a high rate. In such cases, the patient may require sedation and pharmacologic paralysis for efficient delivery of tidal volume. To obviate this problem, *synchronized IMV* (SIMV) is used, whereby the machine-delivered breaths are triggered by the patient’s inspiratory efforts (Fig. 71-9). In between the machine-delivered breaths, a fresh source of gas is available for spontaneous patient breaths. In the
absence of patient effort, the patient receives a backup rate much like in IMV mode. Even with SIMV, ventilator–patient asynchrony can occur, because Vt, inflation pressure, and inspiratory time are determined by the ventilator alone.

**Assist-Control Mode**

In assist-control (AC) mode, each and every patient breath is triggered by pressure or flow generated by patient inspiratory effort and “assisted” with either preselected inspiratory pressure or volume. The rate of respirations is therefore determined by the patient's inherent rate. A backup total (patient and ventilator) obligatory rate is set to deliver a minimum number of breaths. On AC mode with a backup rate of 20 breaths/min, all of the breaths of a patient with an inherent respiratory rate of 15 breaths/min will be assisted by the ventilator, and the patient will receive 5 additional breaths/min. On the other hand, a patient with an inherent rate of 25 breaths/min will receive all 25 breaths assisted. Although useful in some patients, the AC mode cannot be used in the weaning process, which involves gradual decrease in ventilator support.

**Control Variable**

Once initiated, either the tidal volume or the pressure delivered by the machine can be controlled. The machine-delivered breath is thus referred to as either volume-controlled or pressure-controlled (Table 71-11).

With volume-controlled ventilation (VCV), machine-delivered volume is the primary control, and the inflation pressure generated depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance are therefore easily detected from changes observed in inflation pressure. In pressure-controlled ventilation (PCV), the pressure change above the baseline is the primary control, and the tidal volume delivered to the lungs depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance do not affect inflation pressure and may therefore go undetected unless the exhaled Vt is monitored. VCV and PCV have their own advantages and disadvantages (see Table 71-11). Generally speaking, PCV is more efficient than VCV in terms of amount of tidal volume delivered for a given inflation pressure during ventilation of a lung that has nonuniform time constants, such as asthma. In VCV, relatively less-obstructed airways are likely to receive more of the machine-delivered volume throughout inspiration than relatively more-obstructed airways with longer time constants (Fig. 71-10A). This situation would result in uneven ventilation, higher PIP, and a decrease in dynamic compliance. In PCV, because of a constant inflation pressure that is held throughout inspiration, relatively less-obstructed lung units with shorter time constants would achieve pressure equilibration earlier during inspiration than the relatively more-obstructed areas. Thus, units with shorter TCs would attain their final volume earlier in inspiration, and those with longer TCs would continue to receive additional volume later in inspiration (Fig. 71-10B). This situation would result in more even distribution of inspired gas, delivery of more Vt for the same inflation pressure, and improved dynamic compliance in comparison with VCV.

**Pressure-regulated volume control (PRVC)** combines the advantages of VCV and PCV. In this mode, the Vt and Ti are controlled as primary variables but the ventilator determines the amount of pressure needed to deliver the desired Vt. Inflation pressure is thus adjusted to deliver the prescribed Vt over the Ti, depending on the patient's respiratory compliance and resistance.

**Support Modes**

Pressure-support ventilation (PSV) and volume-support ventilation (VSV) are designed to support the patient’s spontaneous respirations. With PSV, initiation of inspiration is triggered by the patient's spontaneous breath, which is then “supported” by a rapid rise in ventilator pressure to a preselected level. The inspiration is continued until the inspiratory flow rate falls to a set level (generally 25% of peak flow rate) as the patient's lungs fill up. Thus, Ti is controlled by the patient's own efforts. PSV can be combined with SIMV so that any breath above the SIMV rate is supported by PSV. Allowing the patient to control as much of the rate, Vt, and inspiratory time as possible is considered a gentler form of mechanical ventilation than SIMV, in which the Vt (or inflation pressure) and Ti are preset. PSV as the sole source of mechanical ventilator support is often not adequate for patients with severe lung disease; however, it is especially useful in patients in the process of being weaned and in patients who require mechanical ventilation for relatively minor lung disease or for neuromuscular weakness. VSV is similar to PSV, in that all the spontaneous breaths are supported. In VSV, inspiratory pressure to support spontaneous breaths is adjusted to guarantee a preset Vt. If there is a change in respiratory mechanics or patient effort, the inspiratory pressure to support the breath initiated by patient effort is automatically adjusted to deliver the set Vt.

**Inspiratory Phase Characteristics**

Ti, inspiratory flow waveform, and pressure rise time can be adjusted in the inspiratory phase to suit the patient's respiratory mechanics. In PCV, the duration of Ti is directly set in seconds. In VCV, the inspiratory time can be adjusted by adjusting the inspiratory flow (volume/time). The choice of Ti value depends on the respiratory rate, which determines the total duration of each breath, and on the estimation of inspiratory and expiratory time constants. Decreasing the flow rate delivery increases Ti, and vice versa. With an increase in Ti, the pulmonary capillary blood is exposed to a higher level of alveolar Pao2 for a longer time. This is beneficial in diseases with decreased FRC, such as ARDS and pulmonary edema. An increase in Ti also increases

early inspiration: Areas with short time constants fill 

Termination of Inspiration (Cycle)
The two most commonly used inspiratory terminating mechanisms in 
control modes are time-cycled and volume-cycled. With a time-cycled 
ception is terminated after a preselected Ti has elapsed, whereas with volume-cycled breath, the inspiration ends after 
with the PIP held constant for the duration of inspiration. A volume- 
cycled breath can be pressure-limited as a safety mechanism to avoid 
the inspiration-terminating mechanism is set somewhat 
different in support modes. In PSV, the inspiration is set to end after 
the inspiratory flow decreases below a certain percentage (usually 25%) 
peak inspiratory flow. This happens when the patient no longer 
desires to receive additional VT. Such a breath can be termed flow- 
cycled. In volume support mode, inspiration is terminated when the 
patient has received the desired VT.

Expiratory Phase Maneuvers
The most useful expiratory phase maneuver is the application of PEEP, 
which is applied to both the control breath and the assisted breath. The 
most important clinical benefits of PEEP are to recruit atelectatic 
alveoli and to increase FRC in patients with alveolar–interstitial dis 
ees and thereby improve oxygenation. There is growing recognition 
that even a brief disconnection from a ventilator, and therefore having 
zero end-expiratory pressure, can result in significant alveolar dere 
rentment and decline in oxygenation. In patients with obstructive 
lesions in which insufficient exhalation results in air trapping and auto 
PEEP, extrinsic PEEP (that applied through a mechanical device) can 
prevent airway closure during expiration and improve ventilation. 
Other salutary effects of PEEP include redistribution of extravascular 
lung water away from gas-exchanging areas, improved ventilation– 
perfusion relationship, and stabilization of the chest wall. The effect of 
PEEP on lung compliance is variable, depending on the level of PEEP 
provided and the patient’s pulmonary mechanics. By shifting the VT 
to a more favorable part of the pressure-volume curve, PEEP may recruit more alveoli, delay airway closure, and improve lung 
compliance. Excessive PEEP, on the other hand, may lead to overd 
tension of alveoli and reduced compliance. The effect of PEEP in ind 
vidual patients can be ascertained by measuring exhaled VT and 
calculating dynamic compliance. Other deleterious effects of PEEP 
include decreased venous return, increased pulmonary vascular resis 
tance, and decreased cardiac output.

Additional Ventilatory Modalities
Airway Pressure Release Ventilation
Airway pressure release ventilation (APRV) improves oxygenation in 
cases of severe hypoxic respiratory failure resulting from alveolar– 
interstitial disease. This modality applies a CPAP, designated CPAPHIGH, 
to recruit and maintain FRC with brief intermittent release phases of 
CPAPLOW to allow alveolar gas to escape. CPAPHIGH is analogous to PIP, 
and CPAPLOW is similar to setting PEEP. In contrast to the patient 
receiving conventional mechanical ventilation, a patient receiving 
APRV spends the majority of time in the CPAPHIGH phase, which may 
last as long as 3-5 sec with a brief (0.3-0.5 sec) time in the CPAPLOW. 
These atypically long inspiratory times are tolerated because of a 
floating expiratory valve in the ventilator circuit that permits spont 
aneous breathing during CPAPHIGH phase. Therefore, even if CPAPHIGH 
phase can be considered inspiratory and CPAPLOW phase can be con 
sidered expiratory as far as the ventilator is concerned, the patient is 
able to breathe spontaneously during both of these phases. The longer 
ventilator inspiratory times recruit lung units, and the ability to breathe 
spontaneously during this phase allows distribution of gas flow to 
atelectatic lung regions. The outcome benefit of APRV in pediatric 
hypoxemic respiratory failure has not been proven.

High-Frequency Ventilation
Mechanical ventilation at supraphysiologic rates and low tidal 
volumes, known as high-frequency ventilation (HFV), improves gas
exchange in a selected group of patients who show no response to traditional ventilatory modalities. The mechanism of alveolar ventilation in HFV is very different from that in conventional ventilation, in that HFV is less dependent on VT and more dependent on asymmetric velocities and convective dispersion of inspired gas. Patients with severe persistent hypoxic failure are most likely to benefit from HFV. HFV is also helpful in patients with bronchopulmonary fistula and persistent air leaks. The main tenet of HFV is to recruit lung volume with a high MAP and produce smaller fluctuations in alveolar pressure during inspiration and expiration, thus maintaining a satisfactory FRC and reducing alveolar stretch. The 2 most investigated techniques of HFV are high-frequency oscillation (HFO) and high-frequency jet ventilation (HFJV).

The most commonly used HFV modality is HFO, which employs a mechanism to generate to-and-fro air movement. Additional air is dragged in (entrained) through a parallel circuit via a Venturi effect. Air is pushed in during inspiration and actively sucked out during expiration. The main determinants of oxygenation are Fio₂ and MAP, whereas ventilation is determined by changes in pressure (amplitude) from the MAP. Commonly used respiratory frequency varies from 5 Hz (300 breaths/min) in adults and older children, to 6-8 Hz (360-480 breaths/min) in young children, 8-10 Hz (480-600 breaths/min) in infants, and 10-12 Hz (600-720 breaths/min) in newborn and premature babies.

In HFJV, a high-frequency interrupter is interposed between a high-pressure gas source and a small cannula that is incorporated in the endotracheal tube (ET). The cannula propels tiny amounts of gas (jets) at high velocity and high frequency through the ET. An additional amount of gas is entrained from a parallel circuit. Unlike in HFO, expiration occurs passively in HFJV as a result of elastic recoil of the lung and the chest wall. PEEP is set through the parallel circuit by a mechanism to generate to-and-fro air movement. Additional air is dragged in (entrained) through a parallel circuit via a Venturi effect. Air is pushed in during inspiration and actively sucked out during expiration. The main determinants of oxygenation are Fio₂ and MAP, whereas ventilation is determined by changes in pressure (amplitude) from the MAP. Commonly used respiratory frequency varies from 5 Hz (300 breaths/min) in adults and older children, to 6-8 Hz (360-480 breaths/min) in young children, 8-10 Hz (480-600 breaths/min) in infants, and 10-12 Hz (600-720 breaths/min) in newborn and premature babies.

CONVENTIONAL VENTILATOR SETTINGS

**FiO₂**

The shape of the hemoglobin–oxygen dissociation curve dictates that oxygen content in the blood is not linearly related to PaO₂. A PaO₂ value that results in an oxyhemoglobin saturation of 95% is reasonable in most situations, because a higher PaO₂ would cause minimal increase in arterial oxygen content, and a modest (~10 torr) drop in PaO₂ would result in minimal decrease in oxyhemoglobin saturation. In most cases, a PaO₂ value of 70-75 torr is a reasonable goal. Fio₂ values that are higher than those necessary to attain oxyhemoglobin saturations of 95% expose the patient to unnecessary oxygen toxicity. Whenever possible, Fio₂ values should be decreased to a level ≤50.4 as long as oxyhemoglobin saturation remains 95% or above.

**Mode**

The choice of mode of ventilation depends on how much ventilator–patient interaction is desired and the disease entity that is being treated. SIMV or AC is chosen as the control mode, PCV, VCV, or PRVC is chosen as the variable that is to be controlled, and pressure support and volume support are the choices for support modes.

**Tidal Volume and Rate**

As previously discussed, alveolar ventilation, the chief determinant of PaCO₂, is calculated using VT, respiratory rate, and dead space volume. A change in VT results in a corresponding change in VA without affecting the dead space ventilation. A change in respiratory rate will affect the VA as well as the dead space ventilation. As mentioned earlier, the choice of VT and rate depends on the time constant. In a patient with relatively normal lungs, an age-appropriate ventilator rate and a VT of 7-10 mL/kg would be appropriate initial settings. Diseases associated with decreased time constants (decreased static compliance, e.g., ARDS, pneumonia, pulmonary edema) are best treated with small (6 mL/kg) VT and relatively rapid rates (25-40 breaths/min). Diseases associated with prolonged TCs (increased airway resistance, e.g., asthma, bronchiolitis) are best treated with relatively slow rates and higher (10-12 mL/kg) VT. In PCV, the delivered VT depends on the compliance and resistance of the patient’s respiratory system and needs to be monitored to ensure the appropriate amount for a given situation. An inflation pressure of 15-25 cm H₂O is sufficient for most patients, but it may need adjustment, depending on the amount of exhaled Vt observed. It should be emphasized that achieving a “normal” PaCO₂ value is not a goal of mechanical ventilation. Mild hypercapnia (permissive hypercapnia) should be acceptable, especially when one is attempting to limit injurious inflation pressures or Vr’s.

**Inspiratory Time and Expiratory Time**

Inspiratory time and expiratory time are adjusted by setting inspiratory flow rate in VCV and by setting the precise Ti in PCV. Increasing the inspiratory time results in an increase in MAP, improvement in oxygenation in diseases with decreased FRC, and better distribution of VT in obstructive lung disease. Sufficient expiratory time must be provided to ensure adequate emptying of the alveoli.

**Positive End-Expiratory Pressure**

The best level of PEEP depends on the disease entity that is being treated, and it may change in the same patient from time to time. Decisions are often based on the PaO₂/Fio₂ ratio and the measurement of dynamic compliance.

**PATIENT-VENTILATOR ASYNCHRONY**

Patient–ventilator asynchrony occurs when the patient’s respiratory pattern does not match that of the ventilator. This can occur during all phases of respiration. Adverse effects of patient–ventilator asynchrony include wasted effort, ineffective delivery of desired VT, excessive generation of in trathoracic pressure resulting in barotrauma and adverse effects on cardiac output, increased work of breathing, and patient discomfort. Although several mechanisms exist to facilitate patient–ventilator asynchrony, a certain amount of asynchrony is inevitable unless the patient is pharmacologically sedated and paralyzed.

**Triggering the Ventilator**

The patient must be able to trigger the ventilator without excessive effort. Ventilators can be pressure-triggered or flow-triggered. With pressure triggering, the inspiratory valve opens and flow is delivered when a set negative pressure is generated within the patient–ventilator circuit during both inspiration and expiration. The amount of pressure required to trigger an inspiration depends on the pressure trigger sensitivity. In flow triggering, the ventilator provides a base flow of gas through the ventilator–patient circuit. When a flow sensor on the expiratory limb of the patient–ventilator circuit detects a decrease in flow as a result of the patient’s inspiratory effort, the inspiratory valve opens and a ventilator breath is delivered. The degree of change in flow required to trigger an inspiration depends on the flow trigger sensitivity. Flow triggering is considered to be more comfortable, primarily because the patient receives some flow prior to triggering the ventilator, in contrast to pressure triggering, in which no flow is provided until the ventilator breath is triggered. Increasing the trigger sensitivity by decreasing the change in either pressure or flow needed to trigger an inspiration decreases the work of breathing. However, reducing the required pressure or flow excessively could result in accidental triggering and unwanted breaths by turbulence caused by condensation in the ventilator circuit, ET leaks, or cardiac oscillations.

**Selection of Appropriate Inspiratory Time**

The duration of Ti should match the patient’s own inspiratory phase. If Ti is too long, the patient's drive to exhale may begin before the ventilator breath has cycled off. When this occurs, exhalation occurs against inspiratory flow and a closed exhalation valve, resulting in increased work of breathing, excessive rise in intrathoracic pressure, and discomfort. If Ti is too short, the patient may be still inhaling when a ventilator breath has cycled off. This can cause patient–ventilator asynchrony, a certain amount of asynchrony is inevitable unless the patient is pharmacologically sedated and paralyzed.
individual patient observations and according to the type of lung disease present. In patients with severe lung disease (both obstructive and restrictive), unnatural Ti and Te values may have to be selected, as discussed earlier. In such situations, adequate analgesia, sedation, and, in extreme cases, neuromuscular blockade may be needed.

**Selection of Inspiratory Flow Pattern**

In VCV, inappropriate flow may be another source of patient–ventilator dyssynchrony. After initiation of inspiration, if the set amount of flow is inadequate to meet patient demand, a state of “flow starvation” occurs, resulting in excessive work of breathing and discomfort. Such cases may require a decelerating inspiratory flow pattern, in which a higher flow is provided in the beginning of inspiration and less toward the end as the lungs fill up. On the other hand, such a pattern may be uncomfortable for a patient who desires more gradual alveolar filling. The selection of inspiratory flow pattern should be based on the individual patient’s respiratory mechanics. In PCV and PSV, the inspiratory rise time determines the manner in which the airway pressure is raised and Vt delivered. Considerations for choosing the appropriate rise time in PCV and PSV are similar to those for choosing the inspiratory flow pattern in VCV.

**Use of Support Modes**

As much as possible, a conscious patient should be allowed to have spontaneous breaths that are supported by either PSV or VSV. This approach minimizes the mandatory breaths generated by the ventilator that are beyond the patient’s control to modulate. Therefore, continued assessments should be made to determine whether the patient is able to maintain ventilatory requirements more in support modes and less in control modes.

**Use of Sedation and Pharmacologic Paralysis**

Having a conscious but comfortable patient is a desirable goal during mechanical ventilation. Spontaneous breaths with good muscle tone and presence of cough are important for adequate clearance of tracheobronchial secretions. The patient’s ability to indicate distress is also important in identifying and preventing potential injurious factors. In certain situations, management of patient–ventilator asynchrony assumes far greater importance when the asynchrony is causing unacceptable derangement of gas exchange and ventilator-induced lung injury. Both alveolar interstitial lung pathology and obstructive airway diseases may necessitate unnatural and uncomfortable settings for respiratory rate, Ti, and inflation pressures. In such situations, deep sedation is often necessary. Benzodiazepines and opiates are the agents most commonly used for this purpose. In extreme situations, pharmacologic paralysis with a nondepolarizing agent, such as vecuronium, is required to abolish any patient effort and respiratory muscle tone. When pharmacologic paralysis is used, deep sedation must be ensured so that the patient does not sense pain and discomfort. Pharmacologic sedation and paralysis can ensure total control of the patient’s ventilation by mechanical means and may result in lifesaving improvement in gas exchange with reduction in inflation pressures. However, long-term use of such agents may be associated with undesirable consequences and higher morbidity. The risk of inadequate tracheobronchial secretions and atelectasis is potentially greater. Long-term use of pharmacologic sedation may be associated with chemical dependency and withdrawal manifestations, and prolonged neuromuscular blockade is associated with neuromyopathy in critically ill patients. The benefits of sedation and pharmacologic paralysis therefore should be carefully balanced with the risks, and periodic assessments should be made to determine the need for their continuation.

**Cardiopulmonary Interactions**

Mechanical ventilation can have both salutary as well as adverse effects on cardiac performance. By decreasing oxygen consumption necessary for work of breathing, oxygen supply to vital organs is improved. Positive-pressure breathing decreases left ventricular afterload, thus enhancing stroke volume and cardiac output in patients with failing myocardium (e.g., myocarditis). On the other hand, the decreased systemic venous return may further compromise stroke volume in hypovolemic patients. Such patients will require intravascular fluid loading. Also an increase in pulmonary vascular resistance (PVR) as a result of positive intrathoracic pressure may result in further uncompensation of a poorly performing right ventricle. PVR is at its lowest value at an optimum FRC. When FRC is too low or too high, PVR (and therefore the right ventricular afterload) is increased. Both desirable and undesirable effects of cardiopulmonary interactions may coexist and require ongoing assessment and necessary interventions.

**MONITORING RESPIRATORY MECHANICS**

**Exhaled Tidal Volume**

Exhaled tidal volume (Vte) is measured by a pneumotachometer in the ventilator circuit during exhalation. In VCV, part of the machine-delivered volume may leak out during inspiration and therefore never reach the patient. Measurement of Vte more accurately describes the Vt that is contributing to the patient’s alveolar ventilation. In PCV, the Vte depends on the patient’s respiratory system compliance and resistance, and therefore offers valuable diagnostic clues. A decrease in Vte during PCV is indicative of either decrease in compliance or increase in resistance and is helpful in directing the clinician to appropriate investigation and management. An increase in Vte is indicative of improvement and may require weaning of inflation pressures to adjust the Vte.

**Peak Inspiratory Pressure**

In VCV and PRVC, the PIP is the secondary variable determined by the patient’s respiratory system compliance and resistance. An increase in PIP in these modes is indicative of decreased compliance (e.g., atelectasis, pulmonary edema, pneumothorax) or increased resistance (e.g., bronchospasm, obstructed ET). During VCV and PRVC, decreasing the respiratory rate or prolonging the Ti will result in a lower PIP in patients with prolonged time constants because more time will be available for alveoli to fill. In such patients, a decrease in PIP suggests increased compliance or decreased resistance of the respiratory system.

**Respiratory System Dynamic Compliance and Static Compliance**

The changes in PIP during VCV and PRVC, and in Vte during PCV, are determined by Cdyn of the respiratory system (lung and chest wall). Dynamic compliance is calculated as follows:

\[ C_{dyn} = \frac{V_{te}}{(P_{PEEP} - P_{plat})} \]

It takes into account both the flow-resistive and the elastic properties of the respiratory system. Changes in Cdyn can be used to assess effects of different levels of PEEP as tidal ventilation is shifted along the slope of the volume-pressure curve (see Fig. 71-8). An increase in PEEP in alveolar-interstitial diseases (increased elastance), resulting in an increase in Cdyn suggests alveolar recruitment, whereas a decrease in Cdyn may indicate overdistention. Similarly, in obstructive diseases (increased resistance), adjustment in PEEP levels to ameliorate airway collapse during exhalation can be guided by monitoring Cdyn. To assess only the elastic recoil of the lung, measurement of Cstat when there is no airflow is required. This measurement is performed by using an inspiratory hold maneuver with the patient under neuromuscular blockade and observing pressure-time and flow-time waveforms (Fig. 71-11). During this maneuver, inspiratory flow ceases while the expiratory valve continues to remain closed, thus allowing pressure to equilibrate throughout the ventilator circuit and the patient’s lungs. This pressure, referred to as the plateau pressure (Pplat), is reflective of alveolar pressure. Cstat is calculated as follows:

\[ C_{stat} = \frac{V_{te}}{(P_{plat} - P_{PEEP})} \]

The difference between Cdyn and Cstat is attributable to airway resistance. This difference is minimal in alveolar-interstitial diseases but substantial in airway obstruction.
Evidence shows that in patients with severe acute hypoxemic respiratory failure, cytokines are released, exacerbating the injury and promoting fluid and protein transudation in the alveoli. Inflammatory mediators imbalance between alveolar epithelial and capillary endothelial cells, causing volutrauma and barotrauma. This volutrauma and barotrauma can lead to disruption of tight junctions in the lung, thereby delaying airway closure during exhalation and improving alveolar emptying.

Assessment of Auto-PEEP

Auto-PEEP is assessed with the use of an expiratory pause maneuver in which inspiration is delayed and alveolar pressure is allowed to equilibrate with the airway. In diseases with airway obstruction, insufficient alveolar emptying may occur if exhalation time is not adequate. The alveolar pressure in excess of the set PEEP at the completion of the expiratory pause is measured as auto-PEEP or intrinsic PEEP. Auto-PEEP can have adverse effects on ventilation and hemodynamic status. It can be managed by decreasing the respiratory rate or inspiratory time and thus allowing greater time for exhalation. Auto-PEEP may also be managed by increasing the set PEEP ("extrinsic" PEEP), thereby delaying airway closure during exhalation and improving alveolar emptying.

Assessment of Dead Space Ventilation

Positive pressure ventilation and application of PEEP may result in a decrease in venous return, cardiac output, and, therefore, also the pulmonary perfusion. Ventilation of poorly perfused alveoli results in dead space ventilation, which does not contribute to gas exchange. The dead space–VT fraction can be calculated with the following equation:

\[ \frac{V_d}{VT} = \left( \frac{P_{ACO_2} - P_{ECO_2}}{P_{ACO_2}} \right) + \frac{P_{ACO_2}}{P_{ACO_2}} \]

Normal \( \frac{V_d}{VT} \) is 0.33. Increased \( \frac{V_d}{VT} \) is indicative of poorly perfused alveoli. Patients with increased \( \frac{V_d}{VT} \) may require intravascular volume infusion or other means of augmenting the cardiac output to improve pulmonary perfusion. The \( \frac{V_d}{VT} \) fraction is calculated and displayed by commercially available capnographs, which measure endotracheal \( P_{CO_2} \) continuously.

**VENTILATOR-INDUCED LUNG INJURY**

Like most medical therapies, mechanical ventilation can be harmful if appropriate principles are not followed. Lung volumes that are too high or too low should be avoided. In attempting to recruit and maintain FRC, the clinician must be careful not to overdistend alveoli. Excessive PIP and VT can lead to unwelcome stress and strain on alveolar walls. This volutrauma and barotrauma can lead to disruption of tight junctions between alveolar epithelial and capillary endothelial cells, causing fluid and protein transudation in the alveoli. Inflammatory mediators and cytokines are released, exacerbating the injury and promoting exudative fluid formation. Decreased production and inactivation of surfactant result in atelectasis and further impairment of gas exchange. Evidence shows that in patients with severe acute hypoxemic respiratory failure, avoidance of VT \( \geq 10 \text{ mL/kg} \) and \( P_{PEEP} \geq 30 \text{ cm H}_2\text{O} \) limits diffuse alveolar damage.

Insufficient PEEP is another important mechanism of ventilator-induced lung injury. Alveoli that are recruited during inspiration must remain open during expiration; if they do not, atelectrauma occurs, which is defined as undesirable shear stress on alveolar walls as they are opened and closed repeatedly. Therefore, the ideal PEEP for a patient should maximize the number of open alveoli and minimize the number of overdistended alveoli. Careful adjustments of PEEP may also permit the clinician to wean a patient from a high inspired oxygen concentration, another potential source of lung injury (oxytrauma). Though most patients receive an inspired oxygen concentration of 100% during endotracheal intubation and at the beginning of mechanical ventilation, increasing PEEP to recruit alveoli without overdistention should be quickly instituted to improve oxygenation and permit weaning of the Fi\( O_2 \). Although an Fi\( O_2 \) value below which there is no risk of oxygen toxicity is unknown, most clinicians aim for a value <0.6.

**Ventilator-Associated Pneumonia**

The pathophysiology of ventilator-associated pneumonia (VAP) is multifactorial. Aspiration of oral and/or gastric secretions, colonization of ETs, and suppression of cough reflexes with sedation all play a role. New-onset fever and leukocytosis accompanied by demonstration of an infiltrative process by chest radiographs are consistent with a diagnosis of VAP. This complication can lead to worsened gas exchange, increased duration of ventilation, and even death. Elevation of the head of the bed to 30 degrees after initiation of mechanical ventilation and use of a protocol for oral decontamination during mechanical ventilation are two means of reducing the risk for VAP. The most effective strategy to minimize any of the aforementioned complications is regular assessment of extubation readiness and liberation from mechanical ventilation as soon as clinically possible.

**Weaning**

Weaning from mechanical ventilation should be considered as a patient's respiratory insufficiency begins to improve. Most pediatricians favor gradual weaning from ventilator support. With SIMV, the ventilator rate is slowly reduced, allowing the patient's spontaneous breaths (typically assisted with pressure or volume support) to assume a larger proportion of the minute ventilation. When the ventilator rate is low (<5 breaths/min) such that its contribution to minute ventilation is minimal, assessment of extubation readiness is performed. An alternative method of gradual weaning is transition to a pressure support mode of ventilation. In this mode, no ventilator rate is set, allowing all triggered breaths to be assisted with pressure support. The clinician reduces the pressure support slowly to a low value (<5–10 cm H\( O_2 \)), at which point assessment of extubation readiness is performed. During either technique, weaning should be halted if tachypnea, increased work of breathing, hypoxemia, hypercapnia, acidosis, diaphoresis, tachycardia, or hypotension occurs.

The most objective means of assessing extubation readiness is a spontaneous breathing trial (SBT). Prior to performance of an SBT, a patient should be awake with intact airway reflexes, capable of handling oropharyngeal secretions, and with stable hemodynamic status. In addition, gas exchange should be adequate, defined as a Pa\( O_2 \) >60 mm H\( g \) while receiving an Fi\( O_2 \) <0.4 and PEEP ≤5 cm H\( O_2 \). If these criteria are present, a patient should be started on CPAP with minimal or no pressure support (≤5 cm H\( O_2 \)). If this SBT is tolerated without episodes of respiratory or cardiovascular decompensation, successful extubation is likely. Some neonates and small children cannot be calmed or consoled long enough to complete the SBT. In this situation, extubation readiness must be assessed on a low level of ventilator support. Data suggest that there is a low risk of extubation failure if the patient’s respiratory physiology is within normal limits and has stable hemodynamic status with adequate gas exchange and spontaneous VT >6.5 mL/kg while receiving <20% of total minute ventilation from the ventilator. Certain patient populations are at increased risk for extubation failure, such as young infants, children mechanically ventilated for >7 days, and patients with chronic respiratory or neurologic conditions. These children often benefit from transition to a noninvasive form of positive pressure ventilation (e.g., high-flow nasal cannula, CPAP, or BiPAP).

![Figure 71-11 Alveolar pressure is best determined by measurement of plateau pressure (\( P_{plat} \)). Inspiration is paused for an extended period, and alveolar gas pressure is allowed to equilibrate with the ventilator circuit pressure. Airway pressure at the end of the inspiratory pause is \( P_{PEEP} \). The difference between peak inspiratory pressure (PIP) and \( P_{PEEP} \) is to overcome flow-resistive properties of the lung, whereas \( P_{PEEP} \) reflects the pressure needed to overcome elastic properties of lung and chest wall.](image-url)
delivered via nasal prongs or face mask to increase the odds of successful extubation. The likelihood of postextubation upper airway obstruction, the most common cause of extubation failure in children, cannot be predicted on the basis of an SBT result or bedside measurements of physiologic variables. Traumatic endotracheal intubation and subglottic swelling from the ET irritation, especially in patients who exhibit agitation while receiving mechanical ventilation, are common causes of airway narrowing after extubation. Administration of intravenous corticosteroids (dexamethasone 0.5 mg/kg every 6 hr for 4 doses prior to extubation) has been shown to minimize the incidence of postextubation airway obstruction. In patients in whom postextubation airway obstruction develops, the need for re-intubation may be obviated by administration of nebulized racemic epinephrine and heliox.

71.2 Long-Term Mechanical Ventilation

See Chapter 418.
**Bibliography**

Changes in 2011 Guidelines for Field Triage

Children Requiring Pediatric Trauma Center Care

Patients with serious injury to >1 organ or system
Patients with 1-system injury who require critical care or monitoring in an intensive care unit
Patients with signs of shock who require >1 transfusion
Patients with fracture complicated by suspected neurovascular or compartment injury
Patients with fracture of the axial skeleton
Patients with ≥2 long-bone fractures
Patients with potential replantation of an extremity
Patients with suspected or actual spinal cord or column injury
Patients with head injury with any 1 of the following: orbital or facial bone fracture, cerebrospinal fluid leak, altered state of consciousness, changing neurologic signs, open-head injury, depressed skull fracture, requiring intracranial pressure monitoring, patients suspected of requiring ventilator support.

To be done up to 3 hours after injury, when faced with multiple casualties and limited resources, the treatment may be decided in an organized manner that maximizes the potential for survival and the least potential for complications. In such cases, a rapid survey of the patient's injuries may help to determine whether the child requires critical care or monitoring. We recommend the following criteria to be used for triage of children in the field: (1) presence of shock, (2) presence of a significant injury that is time-sensitive, (3) presence of a major head injury, and (4) presence of a major musculoskeletal injury.

Assess anatomy of injury

Step Two

| All penetrating injuries to head, neck, torso and extremities proximal to elbow or knee |
| Chest wall instability or deformity (e.g., flail chest) |
| Two or more proximal long bone fractures |
| Crushed, degloved, mangled, or pulseless extremity |
| Amputation proximal to wrist or ankle |
| Pelvic fractures |
| Open or depressed skull fracture |
| Paralysis |

Assess mechanism of injury and evidence of high-energy impact

Step Three

| Falls |
| Adults: ≥20 feet (one story is equal to 10 feet) |
| Children*: ≥10 feet or two or three times the height of the child |
| High-risk auto crash |
| Intrusion,** including roof: ≥12 inches occupant site; ≥18 inches any site |
| Ejection (partial or complete) from automobile |
| Death in same passenger compartment |
| Vehicle telemetry data consistent with a high risk of injury |
| Auto vs. pedestrian/bicyclist thrown, run over, or with significant (>20 mph) impact†† |
| Motorcycle crash ≥20 mph |

Assess special patient or system considerations

Step Four

| Older adults¶¶ |
| Risk of injury/death increases after age 55 years |
| SBP <110 might represent shock after age 65 years |
| Low impact mechanisms (e.g., ground level falls) might result in severe injury |
| Children |
| Should be triaged preferentially to pediatric capable trauma centers |
| Anticoagulants and bleeding disorders |
| Patients with head injury are at high risk for rapid deterioration |
| Burns |
| Without other trauma mechanism: triage to burn facility*** |
| With trauma mechanism: triage to trauma center*** |
| Pregnancy > 20 weeks |
| EMS provider judgment |

When in doubt, transport to a trauma center

 starred criteria in Step One or mechanism identified in Step Two triggers a “yes” response.

† Trauma centers are designated Level I-IV. A Level I center has the greatest amount of resources and personnel for care of the injured patient and provides regional leadership in education, research, and prevention programs. A Level II facility offers similar resources to a Level I facility, possibly differing only in continuous availability of certain subspecialties or frequent prevention, education, and research activities for Level I designation; Level II facilities are not required to be resident or fellow education centers. A level III center is capable of assessment, resuscitation, and emergency surgery, with severely injured patients being transferred to a Level I or II facility. A Level IV trauma center is capable of providing 24-hour physician coverage, resuscitation, and stabilization to injured patients before transfer to a facility that provides a higher level of trauma care.

¶ Any injury noted in Step Two or mechanism identified in Step Three triggers a “yes” response.

** Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.

†† Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact ≥20 mph with a motor vehicle.

¶¶ Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest-level trauma center.

¶¶ Age >55 years.

*** Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

**** Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

* The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.

††† Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.
When the receiving ED is notified before the child’s arrival, the trauma team should also be mobilized in advance. Each member has defined tasks. A senior surgeon (surgical coordinator) or, sometimes initially, an emergency physician leads the team. Team compositions vary somewhat from hospital to hospital; Figure 72-2 shows the model used at Children’s National Medical Center (Washington, DC). Consultants, especially neurosurgeons and orthopedic surgeons, must be promptly available; the operating room staff should be alerted.

Physiologic status, anatomic locations, and/or mechanism of injury are used for field triage as well as to determine whether to activate the trauma team. More importance should be placed on physiologic compromise and less on mechanism of injury. Scoring scales such as the Abbreviated Injury Scale (AIS), Injury Severity Score (ISS), Pediatric Trauma Score (Table 72-3), and Revised Trauma Score use these parameters to predict patient outcome. The AIS and ISS are used together. First, the AIS is used to numerically score injuries—as 1 component and 1 severity within each of 6 ISS body regions: head/neck, face, thorax, abdomen, extremity, and external. The ISS is the sum of the squares of the highest 3 AIS region scores.

**PRIMARY SURVEY**

During the primary survey, the physician quickly assesses and treats any life-threatening injuries. The principal causes of death shortly after trauma are airway obstruction, respiratory insufficiency, shock from hemorrhage, and central nervous system injury. The primary survey addresses the ABCDEs: Airway, Breathing, Circulation, neurologic Deficit, and Exposure of the patient and control of the Environment.

**Airway/Cervical Spine**

Optimizing oxygenation and ventilation, while protecting the cervical spine from potential further injury is of paramount importance. Initially, cervical spine injury should be suspected in any child sustaining multiple, blunt trauma. Children are at risk for such injuries because of their relatively large heads, which augment flexion–extension forces, and weak neck muscles, which predispose them to ligament injuries. To prevent additional spinal injury, the current standard is to immobilize the cervical (and thoracic and lumbar) spine in neutral position with a stiff collar, head blocks, tape or cloth placed across the forehead, torso, and thighs to restrain the child, and a rigid backboard.

Airway obstruction manifests as snoring, gurgling, hoarseness, stridor, and/or diminished breath sounds (even with apparently good respiratory effort). Children are more likely than adults to have airway obstruction because of their smaller oral and nasal cavities, proportionately larger tongues and greater amounts of tonsillar and adenoidal tissue, higher and more anterior glottic openings, and narrower larynxes and tracheas. Obstruction is common in patients with severe head injuries, owing in part to decreased muscle tone, which allows the tongue to fall posteriorly and occlude the airway. With trauma, obstruction can also result from fractures of the mandible or facial bones, secretions such as blood or vomitus, crush injuries of the larynx or trachea, or foreign body aspiration.

If it is necessary to open the airway, a jaw thrust **without head tilt** is recommended. This procedure minimizes cervical spine motion. In an unconscious child, an oropharyngeal airway can be inserted to prevent posterior displacement of the mandibular tissues. A semiconscious child will gag with an oropharyngeal airway but may tolerate a nasopharyngeal airway. The primary survey includes a preliminary survey through a nasopharyngeal airway, followed by endotracheal intubation. End-expiratory carbon dioxide (CO2) detectors help verify accurate tube placement. If these maneuvers plus suctioning do not clear the airway, oral endotracheal intubation is indicated. When endotracheal intubation proves difficult, a laryngeal mask airway can be used as a temporary alternative. A laryngeal mask airway consists of a tube with an inflatable cuff that rests above the larynx and thus does not require placement of the tube into the trachea. Emergency cricothyrotomy is needed in <1% of trauma victims.

**Breathing**

The physician assesses breathing by counting the respiratory rate; visualizing chest wall motion for symmetry, expansion, and accessory muscle use; and auscultating breath sounds in both axillae. Continuous wave form capnography monitoring may also be used as an adjunct; however it is less reliable in patients with shock. In addition to looking visually for cyanosis, pulse oximetry is standard. If ventilation is inadequate, bag-valve-mask ventilation with 100% oxygen must be initiated immediately, followed by endotracheal intubation. End-expiratory carbon dioxide (CO2) detectors help verify accurate tube placement.

Head trauma is the most common cause of respiratory insufficiency. An unconscious child with a severe head injury may have a variety of breathing abnormalities, including Cheyne-Stokes respirations, slow irregular breaths, and apnea.

Although less common than a pulmonary contusion, tension pneumothorax and massive hemotorax are immediately life-threatening (Tables 72-4 and 72-5). **Tension pneumothorax** occurs when air accumulates under pressure in the pleural space. The adjacent lung is compressed, the mediastinum is pushed toward the opposite hemithorax, and the heart, great vessels, and contralateral lung are compressed or

MAJOR FLAIL CHEST

Usually caused by blunt injury resulting in multiple rib fractures

Loss of bone stability of the thoracic cage

Major disruption of synchronous chest wall motion

Mechanical ventilation and positive end-expiratory pressure required

MASSIVE HEMOTHORAX

Must be drained with a large-bore tube

Initiate drainage only with concurrent vascular volume replacement

CARDIAC TAMPOANADE

Beck Triad:
1. Decreased or muffled heart sounds
2. Distended neck veins from increased venous pressure
3. Hypotension with pulsus paradoxus (decreased pulse pressure during inspiration)
   Must be drained

Effect on ventilation depends on size

548  Part IX ♦ The Acutely Ill Child
cutdown (e.g., in the saphenous vein). Ultrasonography can facilitate central venous catheter placement.

Aggressive, intravenous fluid resuscitation is essential early in shock to prevent further deterioration. Isotonic crystalloid solution, such as lactated Ringer injection or normal saline (20 mL/kg), should be infused rapidly. No consensus exists to support the routine use of colloid or hypertonic saline solution for shock (see Chapter 70). When necessary, repeated crystalloid boluses should be given. Most children are stabilized with administration of crystalloid solution alone. However, if the patient remains in shock after boluses totaling 40-60 mL/kg of crystalloid, then 10-15 mL/kg of cross-matched packed red blood cells should be transfused. Although less desirable, type-specific or O-negative cells can be substituted pending availability of cross-matched blood. When shock persists despite these measures, surgery to stop internal hemorrhage is usually indicated.

**Neurologic Deficit**

Neurologic status is briefly assessed by determining the level of consciousness and evaluating pupil size and reactivity. The level of consciousness can be classified using the mnemonic AVPU: Alert, responsive to Verbal commands, responsive to Painful stimuli, or Unresponsive.

Head injuries account for at least 75% of pediatric blunt trauma deaths. Primary direct cerebral injury occurs within seconds of the event and is irreversible. Secondary injury is caused by subsequent anoxia or ischemia. The goal is to minimize secondary injury by ensuring adequate oxygenation, ventilation, and perfusion, and maintaining normal intracranial pressure (ICP). A child with severe neurologic impairment—i.e., with a Glasgow Coma Scale (GCS; see Table 67-3 in Chapter 67) score of 8 or less—should be intubated. Signs of increased ICP, including progressive neurologic deterioration and evidence of transtentorial herniation, must be treated immediately (see Chapter 68). Hyperventilation lowers Paco₂, resulting in cerebral vasoconstriction, reduced cerebral blood flow, and decreased ICP. Brief hyperventilation remains an immediate option for patients with acute increases in ICP. Prophylactic hyperventilation or vigorous or prolonged hyperventilation is not recommended, because the consequent vasoconstriction may excessively decrease cerebral perfusion and oxygenation. Mannitol lowers ICP and may improve survival. Because mannitol acts via osmotic diuresis, it can exacerbate hypovolemia and must be used cautiously. Hypertonic saline may be a useful agent for control of increased ICP in patients with severe head injury and may possibly decrease mortality when compared with mannitol. Neurosurgical consultation is mandatory. If signs of increased ICP persist, the neurosurgeon must decide whether to operate emergently.

**Exposure and Environmental Control**

All clothing should be cut away to reveal any injuries. Cutting is quickest and minimizes unnecessary patient movement.

Children often arrive mildly hypothermic because of their higher body surface area : mass ratios. They can be warmed with use of radiant heat as well as heated blankets and intravenous fluids.

**SECONDARY SURVEY**

During the secondary survey, the physician completes a detailed, head-to-toe physical examination.

**Head Trauma**

A GCS or Pediatric GCS score (see Table 67-3 in Chapter 67) should be assigned to every child with significant head trauma. This scale assesses eye opening and motor and verbal responses. In the Pediatric GCS, the verbal score is modified for age. The GCS helps categorize neurologic disability, and serial measurements identify improvement or deterioration over time. Patients with low scores 6-24 hr after injuries have poor prognoses.

In the ED, CT scanning of the head without a contrast agent has become standard to determine the type of injury in patients with concerning findings. Diffuse cerebral injury with edema is a common and serious finding on CT scan in severely brain-injured children. Focal evacuable hemorrhagic lesions (e.g., epidural hematoma) occur less commonly but may require immediate neurosurgical intervention (Fig. 72-3).

Monitoring of ICP should be strongly considered for children with severe brain injury, particularly for those with a GCS score of 8 or less and abnormal head CT findings (see Chapter 68). An advantage of an intraventricular catheter over an intraparenchymal device is that cerebrospinal fluid can be drained to treat acute increases in ICP. Hypoxia, hypercarbia, hypotension, and hyperthermia must be aggressively managed to prevent secondary brain injury. Cerebral perfusion pressure should be maintained >40 mm Hg at least (although some experts recommend an even higher minimum).

A child with a severe brain injury must be treated aggressively in the ED because it is very difficult to accurately predict long-term neurologic outcome. Compared with adults with similar injuries, children are thought to have better functional outcomes.

**Cervical Spine Trauma**

Cervical spine injuries occur in <3% of children with blunt trauma—with the risk being substantially higher in those with GCS scores ≤8—but they are associated with significant mortality and morbidity. Bony injuries occur mainly from C1 to C4 in children younger than 8 yr. In older children, they occur equally in the upper and lower cervical spine. The mortality rate is significantly higher in patients with upper cervical spine injuries. Spinal cord injury without radiographic (vertebral body) abnormalities (SCIWORA) on plain films or CT may be present. Patients with SCIWORA have neurologic symptoms, and spinal cord abnormalities are nearly always noted on MRI. Approximately 30% of all patients with cervical spine injuries have permanent neurologic deficits.

Evaluation begins with a detailed history and neurologic examination. Identifying the mechanism of injury helps in estimating the likelihood of a cervical spine injury. Both the patient and the paramedic should be asked whether any neurologic symptoms or signs, such as weakness or abnormal sensation, were present before arrival in the...
ED. In a child with neurologic symptoms and normal findings on cervical spine plain radiographs and CT scan, SCIWORA must be considered.

Whenever the history, physical examination, or mechanism of injury suggests a cervical spine injury, radiographs should be obtained after initial resuscitation. The National Emergency X-Ray Utilization Study (NEXUS) cervical spine rule helps identify low-risk patients who may not require radiographs (Table 72-7). The standard series of plain radiographs includes lateral, anteroposterior, and odontoid views. Some centers use cervical spine CT as the primary diagnostic tool, particularly in patients with abnormal GCS scores and/or significant injury mechanisms, recognizing that CT is more sensitive in detecting bony injury than plain radiographs. CT is also helpful if an odontoid fracture is suspected, because young children typically do not cooperate enough to obtain an “open-mouth” (odontoid) radiographic view. Use of cervical spine CT scan must be balanced with the knowledge that CT exposes thyroid tissue to 90-200 times the amount of radiation from plain films. MRI is indicated in a child with suspected SCIWORA and may also be useful in the evaluation of children who remain obtunded.

Rapid diagnosis of spinal cord injury is essential. Initiating high-dose intravenous methylprednisolone within 8 hr of spinal cord injury has been shown to improve motor outcome and remains standard therapy.

**Thoracic Trauma**

Pulmonary contusions occur frequently in young children with blunt chest trauma. A child’s chest wall is relatively pliable; therefore, less force is absorbed by the rib cage, and more is transmitted to the lungs. Respiratory distress may be noted initially or may develop during the first 24 hr after injury.

Rib fractures result from significant external force. They are noted in patients with more severe injuries and are associated with a higher mortality rate. Flail chest, which is caused by multiple rib fractures, is rare in children. Indications for operative management in thoracic trauma are listed in Table 72-8. Table 72-5 shows the differential diagnosis of immediately life-threatening cardiopulmonary injuries.

**Abdominal Trauma**

Liver and spleen contusions, hematomas, and lacerations account for the majority of intra-abdominal injuries from blunt trauma. The kidneys, pancreas, and duodenum are relatively spared because of their retroperitoneal location. Pancreatic and duodenal injuries are more common after a bicycle handlebar impact or a direct blow to the abdomen (Table 72-9).

Although a thorough examination for intraabdominal injuries is essential, achieving it often proves difficult. Misleading findings can result from gastric distention after crying or in an uncooperative toddler. Calm reassurance, distraction, and gentle, persistent palpation help with the examination. Important findings include distention, bruises, and tenderness. Specific symptoms and signs give insight into the mechanism of injury and the potential for particular injuries. Pain in the left shoulder may signify splenic trauma. A lap belt mark across the abdomen suggests a bowel or mesenteric injury. The presence of certain other injuries, such as lumbar spinal fractures and femur fractures, increases the likelihood of intraabdominal injury.

An abdominal CT scan with intravenous contrast medium enhancement rapidly identifies structural and functional abnormalities and is the preferred study in a stable child. It has excellent sensitivity and specificity for splenic (Fig. 72-4), hepatic (Fig. 72-5), and renal injuries, but is not as sensitive for diaphragmatic, pancreatic, or intestinal injuries. Small amounts of free fluid or air or a mesenteric hematoma may be the only sign of an intestinal injury. Administration of an oral contrast agent is not routinely recommended for all abdominal CT scans, but it sometimes aids in identifying an intestinal, especially a duodenal, injury.

Although focused assessment with sonography in trauma (FAST) examination helps detect hemoperitoneum, the variably low sensitivity of this test in children suggests that it should not be used to exclude intraabdominal injury in patients with a high pretest probability for injury. Serial FAST exams over time may be used by skilled ultrasonographers to rule out injury in need of intervention. FAST is most useful in patients who have blunt trauma and are hemodynamically unstable or patients who require operative intervention for nondiagnostic injuries, because in these cases the performance of a CT scan may not be feasible.

Nonoperative treatment has become standard for hemodynamically stable children with splenic, hepatic, and renal injuries from blunt

Pelvic Trauma

Pelvic fractures in children are much less common than in adults, occurring in approximately 4% of children with more severe blunt trauma. Pelvic fractures are typically caused by high forces (e.g., from high-speed motor vehicle crashes or pedestrian impacts) and are often associated with intraabdominal and/or vascular injuries. The pelvis itself forms a ring, and high-force impacts can lead to disruption of this ring. When the ring is disrupted in more than one location, such as the symphysis pubis and the sacroiliac joint, the ring can become unstable and displaced, potentially injuring large pelvic vessels and leading to massive blood loss. Catheter-directed embolization to control bleeding, performed by an interventional radiologist, may be required.

The pelvis should be assessed for stability by means of compression–distraction maneuvers. If instability is noted, immediate external fixation with a pelvis-stabilizing device or a sheet should be applied, and orthopedic consultation sought. A trauma patient with a potential pelvic fracture should receive an anteroposterior pelvic radiograph in the trauma bay, or a CT scan, if highly suspicious. Children without a high-risk clinical finding (i.e., GCS <14; abdominal pain or tenderness, pelvic tenderness, laceration, ecchymosis, or abrasion; positive urinalysis, or femur fracture) or a high-risk mechanism of injury (i.e., unrestrained motor vehicle collision, motor vehicle collision with ejection, motor vehicle collision rollover, auto vs. pedestrian, or auto vs. bicycle) are unlikely to have pelvic fractures, however.

Lower Genitourinary Trauma

The perineum should be inspected, and the stability of the bones of the pelvis assessed. Urethral injuries are more common in males. Findings suggestive of urethral injury include scrotal or labial ecchymoses, blood at the urethral meatus, gross hematuria, and a superiorly positioned prostate on rectal examination (in an adolescent male). Certain pelvic fractures also increase the risk for potential genitourinary injury. Any of these findings is a contraindication to urethral catheter insertion and warrants consultation with a urologist. Retrograde urethrocystogram and CT scan of the pelvis and abdomen are used to determine the extent of injury.

Extremity Trauma

Extremity fractures may initially be missed as clinicians attend to more life-threatening injuries. Thorough examination of the extremities is essential because extremity fractures are among the most frequently overlooked injuries in children with multiple trauma. All limbs should be inspected for deformity, swelling, and bruises; palpated for tenderness; and assessed for active and passive range of motion, sensory function, and perfusion.

Before radiographs are obtained, suspected fractures and dislocations should be immobilized, and an analgesic administered. Splinting a femur fracture helps alleviate pain and may decrease blood loss. An orthopedic surgeon should be consulted immediately to evaluate children with compartment syndrome, neurovascular compromise, open fracture, and most traumatic amputations.

Radiologic and Laboratory Evaluation

Some authorities recommend ordering multiple studies in the ED that include lateral cervical spine, anteroposterior chest, and anteroposterior pelvis radiographs; arterial blood gas analysis; serum lactate determinations; complete blood cell count; electrolyte measurements; blood glucose and blood urea nitrogen measurements; serum creatinine, amylase, and lipase determinations; liver function tests; prothrombin and partial thromboplastin time determinations; blood typing and cross-matching; and urinalysis. One benefit of standardizing the evaluation of patients with major trauma is that fewer decisions need to be made on an individual basis, possibly expediting ED management.

Some of these studies have prognostic importance. A large base deficit is associated with a higher mortality rate, and elevated lactate values correlate with poor prognosis.

There are limitations of standard tests. The lateral cervical spine radiograph can miss clinically significant injuries. Hemoglobin and hematocrit values provide baseline values in the ED, but they may not have yet equilibrated after a hemorrhage. Abnormal liver function test results or elevated serum amylase and lipase values may be noted in patients with significant abdominal trauma, but most patients with significant trauma to the abdomen already have clinical indications for CT scanning or surgery. The majority of previously healthy children have normal coagulation profiles; these may become abnormal after major head trauma. Although routine urinalysis or dipstick urine testing for blood has been recommended for children, other data suggest that this evaluation may be unnecessary in patients without gross hematuria, hypotension, or other associated abdominal injuries.
Clinical prediction rules that combine patient history with physical exam findings have been developed to identify those at low risk of injury for whom specific radiographic and laboratory studies may not be necessary. The NEXUS C-spine rule is a sensitive, easily applicable rule that was validated for adults and children, although the younger population was smaller (see Table 72-7). Several clinical prediction rules have been developed to identify children at low risk of traumatic brain injury (Table 72-10). Another clinical prediction rule has been developed to identify children at very low risk of clinically-important intra-abdominal injuries following blunt trauma (Table 72-11). Although this rule has a negative predictive value of 99.9%, it needs to be externally validated before widespread implementation.

Psychological and Social Support

Serious multisystem trauma may result in significant long-term psychological and social difficulties for the child and family, particularly when there is a major head injury. Like adults, children are at risk for depressive symptoms and posttraumatic stress disorder. Caregivers face persistent stress and have been noted to have more psychological symptoms. Psychological and social support, during the resuscitation period and afterwards, is extremely important. Parents often prefer to be offered the choice to be present during resuscitations. A member of the resuscitation team should be made responsible for answering the family’s questions and supporting them in the trauma room.

Bibliography is available at Expert Consult.
nonpharmacologic or additional pharmacologic methods of analgesia and anxiolysis are required for a young, frightened, or uncooperative child. The wound should be examined under proper light to enable identification of foreign bodies or damage to vessels, nerves, or tendons.

Many lacerations, especially heavily contaminated ones, benefit from irrigation, with either water or sterile saline, to reduce the risk of infection. It is important to recognize that many traumatic lacerations treated in the ED or office are only minimally contaminated, containing less than 10^2 bacterial colonies. In fact, in one of the few human studies on irrigation, irrigation did not decrease the infection rate of minimally contaminated scalp or facial lacerations in patients who presented to an ED within 6 hr of injury. Another concern is that higher-pressure irrigation may actually increase tissue damage, making the wound and adjacent tissue more susceptible to infection and delaying healing. These caveats notwithstanding, irrigation has benefits, although which technique to use—that is, which device, what size syringe, what size needle, which solution, how much volume, how much pressure—remains to be determined. These features may vary for different types of lacerations. In heavily contaminated wounds, the benefit of higher-pressure irrigation likely outweighs the harm of tissue damage. For heavily contaminated lacerations, a typical recommendation is to use a 35- to 65-mL syringe attached to a plastic splatter shield, or a 19-gauge needle if a splash shield is unavailable, and to irrigate with approximately 100 mL of solution per centimeter of wound. Conversely, for relatively clean wounds, lower-pressure irrigation minimizes tissue damage, which may be more important for outcome than any decrease in bacterial clearance that may ensue. Debridement of devitalized tissue with higher-pressure irrigation, scrubbing, or surgical excision can also be necessary in certain cases, such as crush injuries.

Most lacerations seen in the pediatric ED or office should be closed primarily. Contraindications to primary closure (e.g., certain bite wounds) do exist (see Chapter 724). Although it is commonly accepted that the time from injury to repair should be as brief as possible to minimize the risk of infection, there is no universally accepted guideline as to what length of time is too long for primary wound closure. Also, this length of time varies for different types of lacerations. A prudent recommendation is that higher-risk wounds should be closed within 6 hr at most after the injury but that some low-risk wounds (e.g., clean facial lacerations) may be closed as late as 12-24 hr.

Many lacerations can be closed with simple, interrupted, 4-0, 5-0, or 6-0, nonabsorbable sutures. For lacerations under tension, horizontal or vertical mattress sutures, which provide added strength and may evert the wound edges better, can be used instead. For lacerations in cosmetically significant areas, a running intradermal stitch may produce a less conspicuous, more aesthetic scar than simple or mattress skin sutures, which can leave unattractive track marks. Deeper lacerations may need repair with an absorbable dermal and/or fascial layer. Other complex lacerations, such as those involving the ear, eyelid, nose, lip, tongue, genitalia, or fingertip, sometimes require more advanced techniques as well as subspecialty consultation.

Staples, topical skin adhesives, and surgical tape are acceptable alternatives to sutures, depending on the laceration’s location and the healthcare provider’s preference. Staples are particularly useful for lacerations of the scalp, where the appearance of the scar tends to be less important. Topical skin adhesives (octylcyanoacrylates or butylcyanoacrylates) are ideal for linear, relatively superficial lacerations that have been tied around a part of the body and has rubbed against the skin. These injuries should alert the clinician to the likelihood of nonaccidental (including self-inflicted) trauma.

Treatment

All abrasions should be cleansed thoroughly, and any debris or foreign material removed. If debris is not removed, abnormal skin pigmentation, known as post-traumatic tattooing, can occur and can be difficult to treat. A nonadherent occlusive dressing or a topical antibiotic and conventional dressing should be applied. Tetanus prophylaxis should be administered, if indicated (see Chapter 211). Large and/or deep abrasions that have not healed in a few weeks require consultation with a plastic surgeon for more advanced care.

Bibliography

High-altitude illness represents a spectrum of clinical entities with neurologic and pulmonary manifestations that overlap in their presentations and share common elements of pathophysiology. Acute mountain sickness (AMS) is the relatively benign and self-limited presentation, whereas high-altitude pulmonary edema (HAPE) and high-altitude cerebral edema (HACE) represent the potentially
life-threatening manifestations. Children are at risk of developing these conditions as they travel to high mountainous locations with their families pursuing outdoor recreation, tourism, or relocation to high-altitude communities.

In 1987, it was estimated that more than 1 million visitors of all ages travelled annually to the remote high mountain ranges of Asia, Africa, and South America, and approximately 35 million visitors travelled annually to high-altitude recreation areas in the western United States; today these numbers are likely to be underestimations. Given the large number of families travelling to high-altitude mountain locations worldwide and the potential for 25% of those travelling to even moderate altitudes to develop altitude-related symptoms, this has become a significant public health issue. Significant morbidity among children travelling with their families to high altitude locations warrants improved education of the populations at risk and the clinicians who care for them.

**ETIOLOGY**

**Definitions**
The altitude threshold where clinical illness may begin to occur is 1,500 meters (~4,900 ft). At this altitude a mild impairment in oxygen transport begins, yet altitude illness is relatively rare until higher elevations are reached. Children with underlying medical problems that impair oxygen transport may be predisposed to developing altitude illness at these lower levels. At moderate high altitude, 2,500-3,500 meters (~8,000-11,500 feet) arterial oxygen saturation (SaO₂) is generally well maintained; however, mild tissue hypoxia may occur as a result of low arterial oxygen partial pressure (Pao₂) and altitude illness becomes common after rapid ascent over 2,500 m. This is the altitude range that most people visit and the elevation of many popular ski resorts in the United States, thus the most common range to find the greatest number of altitude illness cases. Very high altitude, 3,500-5,500 meters (~11,500-18,000 feet) is associated with the most serious altitude illness, as SaO₂ falls below 90%. Here saturations fall on the steep portion of the oxyhemoglobin dissociation curve, and marked desaturation may occur with relatively small increases in altitude. At these heights severe hypoxemia is seen with sleep, exercise and illness. HAPE and HACE are most common in this environment. *Extreme high altitude*, above 5,500 meters (~18,000 feet) generally results in severe altitude illness during acute ascent without supplemental oxygen. Acclimatization at intermediate altitudes is required to reach extreme altitudes. Complete acclimatization is not possible, and long visits in this range result in progressive deterioration.

**Environmental Considerations**
The partial pressure of oxygen (P<sub>O2</sub>) in the atmosphere decreases log-arithmically as geographic altitude rises, but oxygen remains a constant 20.93% of the barometric pressure. The degree of hypoxia is related to the geographic altitude and the local variability of barometric pressure. The shape of the earth is slightly flat at the poles and bulging at the equator. The atmospheric envelope that surrounds the earth has a similar shape; thus the barometric pressure and the relative altitude are lower at higher latitudes than at the equator. The atmospheric envelope also develops seasonal variations in its local thickness, resulting in barometric pressures that are lower and relative altitudes that are higher during the winter season. Local weather can also have a significant effect on barometric pressure from day to day. A strong low-pressure front can reduce the barometric pressure 10-20 mm Hg and result in a significant temporary increase (150-500 m) in relative altitude.

**GENERAL EFFECTS OF HYPOBARIC HYPOXIA**
Arterial oxygen saturation falls with increasing altitude, eventually triggering central chemoreceptor responses to produce hyperventilation in an attempt to normalize oxygen saturation; relative hypoventilation exacerbates the hypoxemia of high-altitude exposure. During sleep, periodic breathing associated with high-altitude exposure may result in periods of apnea, causing further arterial oxygen desaturation. Fluid homeostasis often shifts at altitude, resulting in a generalized fluid retention and redistribution into intracellular and interstitial spaces manifested by peripheral edema, decreased urinary output, and impaired gas exchange.

**Acclimatization**
Gradual ascents allowing for acclimatization over several weeks have allowed successful summiting of many of the world’s highest peaks without supplemental oxygen. Without this gradual approach, rapid exposure to extreme altitude results in loss of consciousness and asphyxia in a matter of minutes. Children may acclimatize at least as well if not better than adults when comparing heart rate and arterial saturation of children 7-9 yr of age to their parents during a slow ascent.

Some of the responses to hypoxia are mediated at the molecular level by hypoxia inducible factor (HIF). This transcriptional activator orchestrates the expression of hundreds of genes in response to both acute and chronic hypoxic conditions. Acclimatization begins at the altitude that causes the oxygen saturation of arterial blood to fall below sea level values. Most healthy, unacclimatized visitors to high altitude will not experience a significant drop in oxygen saturation (SaO₂ < 90%) until they reach elevations above 8,000 feet. Children with preexisting conditions that reduce oxygen transport may have altitude intolerance and hypoxic stress at lower levels. Of particular importance are both acute and chronic cardiac and respiratory illnesses. An individual’s inherent ability to acclimatize is also important. Some acclimatize easily without developing clinical symptoms, others may transiently develop AMS during acclimatization, and a few have marked reactions to altitude exposure, fail to acclimatize, and develop severe altitude illness. Previ-ous successful acclimatization may be predictive of future responses for adults in similar conditions but may not be the case for children.

The most important response to acute hypoxia is an increase in minute ventilation. Peripheral chemoreceptors in the carotid bodies respond to hypoxia by signaling the respiratory control center in the medulla to increase ventilation. This decreases alveolar carbon dioxide partial pressure resulting in a corresponding increase of alveolar oxygen tension and arterial oxygenation. This increased ventilation known as the hypoxic ventilatory response (HVR), varies in magni-tude among individuals, may be genetically predetermined, and is related to the ability to acclimatize. A low HVR and relative hypoventilation are implicated in the pathogenesis of both AMS and HAPE, whereas a strong HVR enhances acclimatization. As ventilation increases, a respiratory alkalosis occurs, exerting negative feedback on central respiratory control, limiting further ventilation increase. The kidneys excrete bicarbonate in an effort to compensate for the alkalosis. As the pH normalizes, ventilation rises slowly, reaching a maximum after 4-7 days. *This process is enhanced by acetazolamide, which induces a bicarbonate diuresis.*

Increased sympathetic activity and catecholamine release on ascent result in elevation of heart rate, blood pressure, cardiac output, and venous tone. Except at extreme altitudes, acclimatization results in the resting heart rate gradually returning to near sea level values. *Resting relative tachycardia is evidence of poor acclimatization.*

Hematopoietic acclimatization consists of an increase in hemoglo-bin and the number of red blood cells and increase in 2,3-diphosphoglycerate. After acute ascent, an early increase of up to 15% occurs in hemoglobin concentration primarily from fluid shifting into the extravascular space. Acclimatization leads to an increase in plasma volume and total blood volume. Erythropoietin is secreted in a HIF-mediated response to hypoxemia within hours of ascent, stimulating the production of new red blood cells, which begin to appear in the circulation in 4 or 5 days. Hypoxemia also increase 2,3-diphosphoglycerate, resulting in a rightward shift of the oxyhemoglobin dissociation curve, favoring release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the oxyhe-moglobin dissociation curve caused by the respiratory alkalosis from hyperventilation. The result is a net null change in the oxyhemoglobin curve and an increase in oxygen-hemoglobin binding in the lung, raising SaO₂. Climbers at extreme altitude respond with marked hyperventilation, alkalosis and leftward shift; this leftward shift favors oxygen loading in a hypoxic environment and increases SaO₂. Some
individuals with mutant hemoglobin and high oxygen-hemoglobin affinity have been found to acclimatize more efficiently at moderate altitudes than their normal counterparts.

**ACUTE MOUNTAIN SICKNESS**

**Epidemiology and Risk Factors**

The incidence of high-altitude illness depends on several variables including the rate of ascent, previous altitude exposure, and individual genetic susceptibility. Sleeping altitude, final altitude reached, and duration of stay at altitude are also clear risk factors for AMS development. AMS is very common with rapid ascent. Climbers around the world who ascend quickly (1 or 2 days) from sea level to altitudes of 14,000–20,000 feet have a very high incidence of AMS (27–83%). The rapid ascent profile associated with air travel to high altitude locations also results in high AMS attack rates. Trekkers who fly into the Khumbu region to explore the Mt. Everest area have a higher incidence of AMS (47%) compared with those who walk (23%). Skiers who visit resorts in the western United States from sea level generally fly or drive to the region but sleep at relatively moderate altitudes (6,300–9,700 ft). Among this population, AMS occurs in approximately 25%.

Children have the same incidence of AMS as adults. Individual (genetic) susceptibility for the development of AMS plays a significant role in risk assessment. Most individuals with previous histories of AMS after acute ascent are likely to experience similar symptoms with repeated visits to altitude. While anecdotal clinical experience supports this concept in children, limited data exist regarding recurrent AMS in children. Gender does not affect the incidence of AMS.

**Pathophysiology**

The symptoms of AMS develop several hours after arrival at high altitude, whereas the development of HAPE and HACE generally requires several days of altitude exposure. Because hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness, but rather the initiating factor.

The clinical manifestations of AMS/HACE are primarily the result of central nervous system dysfunction caused by hemodynamic mechanical factors and biochemical mediators of permeability. The central nervous system (CNS) vasodilatory response to hypoxemia causes an increase in cerebral blood flow and volume. Significant elevation of brain volume is observed in moderate to severe AMS and HACE but has not been demonstrated in mild AMS. Hypoxic alteration of CNS vascular autoregulation and hypertension from exercise may increase pressure transmission to the brain's capillary beds resulting in transepidermal leakage and vasogenic edema. HIF-mediated vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation may increase permeability. Both mechanical and biochemical activation of the trimeric vasogenic system have been proposed as the cause of high-altitude headache, the primary symptom of AMS. While vasogenic edema has been implicated in severe AMS and HACE, magnetic resonance imaging (MRI) reveals signal changes in subjects with and without clinical AMS.

Many of the responses to hypoxia and altitude exposure occur both in individuals who develop symptoms and those who remain free of AMS. To address the discrepancy in symptomatic illness, the “tight fit” hypothesis was proposed. This theory suggests that the development of AMS/HACE is the result of a lack of intracranial space to accommodate increasing volume from brain swelling and edema that develop at altitude. The adequacy of the intracranial and intraspinal space to buffer changes in brain and cerebrospinal fluid (CSF) volume is the central concept. Buffering occurs as the intracranial CSF is displaced via the foramen magnum into the space available in the spinal canal, followed by increased CSF absorption and decreased CSF production. Individuals with less CSF buffering capacity have less compliance and are hypothesized to become more symptomatic (develop AMS).

**Diagnosis**

In adults, the symptoms of mild AMS are similar to those of a viral syndrome, an ethanol “hangover,” or simple physical exhaustion. To diagnose AMS, an adult must be in the setting of a recent gain in altitude, be at the new altitude for at least several hours, and report a headache plus at least 1 of the following symptoms: gastrointestinal upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness or lightheadedness, or difficulty sleeping. These symptoms comprise the adult Lake Louise criteria for AMS. The headache may vary from mild to severe; anorexia plus nausea, with or without vomiting, are common. Sleep disturbance caused by periodic breathing is common in all visitors to high altitudes but is exacerbated in the setting of AMS. All the symptoms of AMS can range in severity from mild to incapacitating. Symptoms develop within a few hours after ascent and generally reach maximum severity between 24 and 48 hr, followed by gradual resolution. Most adults become symptom free by the 3rd or 4th day. The vague nature of this presentation has resulted in many misdiagnoses and morbidity among adults. In the setting of recent altitude exposure, these symptoms warrant a presumptive diagnosis of AMS and limitation of further ascent. There are no diagnostic physical signs in cases of mild AMS. Any evidence of CNS dysfunction, such as mild ataxia or altered mentation, is early evidence of HACE. Similarly, while dyspnea on exertion is universal at high altitudes, dyspnea at rest is an early indicator of HAPE.

Among infants and older preverbal children (up to 3 yr of age), AMS is diagnosed using nonverbal criteria. In this age range, AMS is manifested by increased fussiness, decreased playfulness, decreased appetite, and sleep disturbance. In most cases of AMS in very young children, all of these symptoms are present. Fussiness is defined as a state of irritability that is not easily explained by a cause, such as tiredness, wet diaper, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness or muscular tension. Decreased playfulness may be profound. Alterations of appetite may progress to frank vomiting. Sleep disturbance can manifest with either increased or decreased sleep when compared to normal patterns. Most often decreased sleep and the inability to nap are noted.

The diagnosis of AMS in older children with early language skills (ages 4–11 yr) may be made with cautious use of the adult Lake Louise criteria. The language used in this adult questionnaire may be too complex and may underestimate AMS if not understood by the child. This is particularly true for questions regarding headache (the key symptom of AMS) and gastrointestinal symptoms. An age-appropriate modified Lake Louise Score for 4–11 yr old children has been proposed and used in the research setting (Fig. 73-1). Evaluating for the presence of headache can be accomplished by asking if the “head hurts” or by using a visual “faces” pain scale. Gastrointestinal symptoms are evaluated by asking children if they are “hungry” rather than trying to evaluate their appetite.

Many of the symptoms manifested by AMS in children may also result from the disruption of normal routine with travel. A change in environment, sleeping accommodation, or eating options can result in a fussy child. The threshold scores for AMS diagnostic criteria are modified to account for these baseline variations. Parents can easily learn to recognize AMS in preverbal children using the Children’s Lake Louise Score to alert them to the constellation of alterations in fussiness (headache equivalent), appetite, playfulness and sleep in their young child (see Fig. 73-1). Educating parents to recognize the symptoms of AMS in themselves is also important as an ill parent can indirectly compromise a child’s safety.

Other acute illnesses can mimic AMS in young children. It must be emphasized that altered mental status, neurologic abnormalities, breathing difficulty or cyanosis are not part of uncomplicated AMS. Any of these signs warrant immediate medical attention. If serious bacterial illness, a surgical condition, or another problem meriting specific intervention is suspected in a child, descent to lower altitude is recommended to eliminate the confounding variable of altitude illness.

**Periodic Breathing**

Periodic breathing at altitude is common at all ages during sleep, resulting in brief repeated episodes of oxyhemoglobin desaturation. Prepubertal children (9–12 yr old) have similar night-time oxygen

CLLS = FS + E + P + S

The CLLS must be ≥7 with both the FS ≥4 and E+P+S ≥3 to confirm acute mountain sickness.

Fussiness is defined as a state of irritability that is not easily explained by a cause, such as tiredness, hunger, teething or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Please rate your child's typical fussy behavior during the last 24 hr without the benefit of your intervention.

Management

The management of AMS must include strict adherence to the principle that further ascent to a higher sleeping altitude is contraindicated after the symptoms of altitude illness occur. Halting ascent or activity to allow further acclimatization may reverse the symptoms; however, the ascent exacerbates the underlying pathologic processes and may lead to disastrous results. Stopping further ascent and waiting for acclimatization treats most AMS in 1-4 days. Mild cases of AMS may be treated without descent if monitoring by a reliable caregiver is available. In addition to rest, symptomatic therapy includes analgesics and antiemetics. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention mandates descent. Descent (500-1,000 m) is effective treatment for all forms of altitude illness and should be tailored to the individual response. The presence of neurologic abnormalities (ataxia or altered mentation) or evidence of pulmonary edema (dyspnea at rest) mandates descent because these signs indicate a progression of AMS to severe altitude illness.

Supplemental oxygen administration relieves AMS symptoms, including small amounts (1-2 L/min) given during sleep. In the wilderness, oxygen tanks are impractically heavy and are usually unavailable in adequate amounts; therefore, oxygen therapy is usually reserved for the more serious manifestations of high-altitude illness. In resort settings, oxygen may be readily available for use in the hotel or condominium, but use in children is often difficult. Hyperbaric therapy that simulates descent is also effective.

Treatment of headache and nausea can be beneficial during the course of mild AMS, and in many cases this may be all that is necessary. Ibuprofen and acetaminophen are useful for the treatment of high-altitude headache; evidence supports this conservative approach in children as well. For nausea and vomiting, ondansetron oral dissolving tablets may be used.

Acetazolamide is a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis, causing a metabolic acidosis that increases ventilation and arterial oxygenation. This respiratory stimulation improves sleep when the hypoxemia caused by periodic breathing is eradicated by acetazolamide. Acetazolamide accelerates acclimatization and, if

*AMS prophylaxis is not routinely recommended in children. It is indicated when rapid ascent profile is unavoidable or previous altitude illness in child about to undergo similar ascent profile. Doses as low as 1.25 mg/kg every 12 hr have been successful in some children.
†Use not warranted due to risk of adverse effects. Use slow graded ascent or acetazolamide.
§Oxygen and descent are the treatment of choice for severe AMS. If acetazolamide is not tolerated dexamethasone may be used. Oxygen, descent, and dexamethasone should be used in HACE.
In emergency settings where oxygen and descent are not an option, then nifedipine is indicated.
In emergency settings where oxygen and descent are not an option, if nifedipine is not well tolerated, then sildenafil may provide an alternative.

_given early in the development of AMS, rapidly resolves symptoms. The dose for children is 2.5 mg/kg/dose given twice daily to a maximum of 250 mg/dose (Table 73-1). Treatment for 48 hr is usually adequate for resolution of symptoms.

The most common adverse reactions to acetazolamide in adults include paresthesia, polyuria, and taste alterations. Less common reactions include nausea, drowsiness, tinnitus, transient myopia, and, rarely, rash. Acetazolamide is a nonantibiotic sulfa compound that carries a low risk of cross-reactivity for individuals with an allergy to sulfa antibiotics. A history of anaphylaxis or severe skin reactions to any sulfa-containing medication contraindicates the use of acetazolamide. Acetazolamide should be avoided in breastfeeding mothers and pregnant women.

Dexamethasone is an effective alternative treatment for AMS in adults. Although dexamethasone can resolve the symptoms of AMS, it does not play a role in acclimatization and symptoms may recur when the treatment is withdrawn. Adverse reactions to dexamethasone of concern in the pediatric population are pancreatitis, pseudotumor cerebri, and interference with normal growth. While these reactions are generally seen with prolonged use, dexamethasone should be avoided in children for prophylaxis and used for treatment only in extreme situations where alternatives such as descent or oxygen therapy are unavailable. The dosage of dexamethasone is 0.15 mg/kg/dose orally every 6 hr to a maximum of 4 mg per dose.

**Prevention**

Individuals who have a known susceptibility to the development of AMS and those for whom slow ascent is impractical may consider prophylactic medication. *Acetazolamide remains the compound of choice for AMS prophylaxis.* Numerous studies have demonstrated its effectiveness in adults, and 125 mg twice daily starting 24 hr before ascent and continuing for the first 2 days at high altitude is recommended. The recommended dosage of acetazolamide for AMS prophylaxis for children is 2.5 mg/kg/dose orally up to 125 mg total given twice daily. Ibuprofen when compared to acetazolamide is equally efficacious in preventing headache in adults. Dexamethasone also prevents AMS. However the potential adverse effects in children preclude its use for prophylaxis in this age group. Recommendations for hydration are frequently given in the lay literature, yet no evidence supports this advice. Drinking excessive amounts of free water may lead to hyponatremia and possibly complicate altitude illness.

**HIGH ALTITUDE CEREBRAL EDEMA**

**Epidemiology and Risk Factors**

HACE is rare in children, but it is rapidly fatal if unrecognized. Generally seen in adults with prolonged stays above 3,000 m, HACE is usually associated with concurrent AMS or HAPE, but can occur on its own.

**Pathophysiology**

HACE is regarded as the extreme expression of the same pathophysiology underlying AMS. In patients with HACE, MRI studies reveal white matter changes consistent with vasogenic edema that correlate with symptoms; evidence of cytotoxic edema has also been described.

**Diagnosis**

HACE is differentiated from severe AMS by the presence of neurologic signs. Most common are ataxia and altered mental status including confusion, progressive decrease in responsiveness, and eventually coma. Less common are focal cranial nerve palsies, motor and sensory deficits, and seizures. CT imaging is consistent with edema and increased intracranial pressure. MRI shows a high T2 signal in the white matter, specifically in the splenium of the corpus callosum, with diffusion-weighted technique.

**Management**

Descent remains the most effective treatment for HACE. Supplemental oxygen, if available, is useful especially if descent is not possible or delayed. Portable hyperbaric treatment is beneficial but its use should not delay descent if feasible. Dexamethasone should be administered at a dose of 0.15 mg/kg per dose given orally every 6 hr. The few mild cases of HACE reported in children have recovered with dexamethasone and descent.

**HIGH ALTITUDE PULMONARY EDEMA**

**Epidemiology and Risk Factors**

HAPE is a noncardiogenic pulmonary edema characterized by extravasation of intravascular fluid into the extravascular space of the lung.
HAPE generally occurs in the setting of recent ascent, most often at altitudes above 2,500 m, but in some cases at altitudes as low as 1,740 m. Among children, HAPE occurs in 2 distinct settings. **Type I HAPE** (or simply HAPE) occurs in a child who resides at low altitude who travels to high altitude. **Type II HAPE** (also termed reentry HAPE or reascent HAPE) affects children who reside at high altitude but become ill on their return home after descent to lower altitudes. HAPE may also occur in children who develop acute respiratory illnesses that exacerbate hypoxia at high altitude. Fatal outcomes of HAPE in children have been reported. Most mild and moderate cases resolve without difficulty, however if unrecognized and untreated, rapid progression to death can occur, especially when infection or cardiac conditions complicate the illness.

The incidence of HAPE is highly variable, as it depends not only on the altitude attained, but also the speed of ascent and prior history of HAPE. HAPE is significantly less common than AMS and its incidence in children resident at low altitude appears to parallel that among low-altitude-resident adults. HAPE affects male and female children more equally than adults, among whom the observed male predominance appears due to strenuous sport activities and military assignments. The occurrence and even the pathophysiology of HAPE may vary by population and genetic background. Individuals of Tibetan ancestry, resident on the Himalayan plateau and having minimal admixture with other populations, represent the extreme of adaptation to high altitude and rarely experience HAPE. Other native populations residing at high altitude, such as Andeans, do not appear to be protected from HAPE, and certain populations may have genetic polymorphisms associated with pulmonary edema. A number of conditions may predispose a child to HAPE (Table 73-2). Preexisting viral respiratory infections have been linked to HAPE, especially in children. Cardiorespiratory conditions associated with pulmonary hypertension, such as atrial and ventricular septal defects, pulmonary vein stenosis, congenital absence of a pulmonary artery, and obstructive sleep apnea also predispose to HAPE. Down syndrome is also a risk factor for HAPE development, as are previously repaired congenital heart defects and the presence of hypoplastic lungs. Undiagnosed structural cardiopulmonary abnormalities may result in severe hypoxia and/or altitude illness once ascent occurs.

**Physiology**

Alveolar hypoxia results in vasoconstriction of pulmonary arterioles just proximal to the alveolar capillary bed. Hypoxic pulmonary vasoconstriction is a normal physiologic response to optimize ventilation/perfusion (V/Q) matching by redistributing regional pulmonary blood flow to areas of highest ventilation, thereby optimizing arterial oxygenation. Under conditions that result in widespread alveolar hypoxia, extensive pulmonary vasoconstriction will lead to significant elevations in pulmonary arterial pressure; uneven pulmonary vasoconstriction can result in localized overperfusion, increased capillary pressures, distention, and leakage in the remaining vessels. This explains the patchy and heterogeneous edema that is classically observed in HAPE. The combination of pulmonary hypertension and uneven pulmonary vasoconstriction appears to be necessary in the pathogenesis of HAPE. Children and adolescents acutely exposed to high-altitude hypoxia demonstrated pulmonary hypertension, with increases in pulmonary artery pressure inversely related to age. Once the vascular leak occurs and alveolar fluid accumulates, a defect in transepithelial sodium transport impairs the clearance of alveolar fluid and contributes to HAPE.

### Diagnosis

The diagnosis of HAPE is based on clinical findings and their evolution in the context of recent ascent from lower elevation. There is no single diagnostic test or constellation of laboratory findings. Symptoms commonly develop within 24–96 hr, and onset of symptoms often occurs during the first or second night at altitude when hypoxia may be exacerbated during sleep. HAPE generally is not observed beyond 5 days after ascent to altitude (unless additional ascent occurs) because pulmonary vascular remodeling and acclimatization have taken place. The minimum criteria to diagnose HAPE include: recent exposure to altitude, dyspnea at rest, radiographic evidence of alveolar infiltrates, and near-complete resolution of both clinical and radiographic signs within 48 hr after descent or institution of oxygen therapy. Portable ultrasound has been shown useful to diagnose HAPE through the finding of “comet tails,” artifacts created by microreflections of the ultrasound beam within interlobular septae thickened by interstitial and/or alveolar edema.

The symptoms of AMS and HAPE show considerable overlap, and AMS may precede the development of HAPE in approximately half of patients. Frequently patients first exhibit general malaise that may progress to more specific signs of dyspnea at rest, then cardiopulmonary distress. Young children may show agitation and general debility. Older children may complain of headache, and children of all ages frequently experience nausea and vomiting. Cough is a common pulmonary sign. Dyspnea at rest, orthopnea, cyanosis, tachycardia, and chest pain herald worsening compromise, which may advance within hours to production of pink-tinged sputum.

Findings on physical exam frequently are less severe than a patient’s chest radiograph and the hypoxemia on pulse oximetry would predict. Children often appear pale, with or without visible cyanosis. Low-grade fever (<38.5°C [101.3°F]) is common and respiratory rate is generally increased. Auscultation typically reveals rales, usually greater in the right lung than the left on presentation. The radiographic pattern of pulmonary edema can be highly variable, from patchy and peripherally to more homogeneous in severe cases (Fig. 73-2). Often, the right lung shows more radiographic changes of edema than the left. Cardio-megaly is an uncommon finding, but peribronchial and perivascular cuffing are frequent, as well as enlargement of the pulmonary artery.

silhouette and dilation of more peripheral pulmonary arteries. Significant arterial oxygen desaturation, as measured by pulse oximetry, is a consistent finding, with saturations frequently below 75%. A complete blood count often reveals a leukocytosis with a left shift of the granulocyte series.

The differential diagnosis of HAPE includes pneumonia, bronchitis/bronchiolitis, asthma, and other forms of cardiogenic and noncardiogenic pulmonary edema as well as pulmonary embolism. HAPE is most frequently misdiagnosed as pneumonia or a viral respiratory illness, especially when suspicion of altitude-associated pathology is not appropriately high. The presenting signs of cough, dyspnea, and orthopnea, follow by sputum production can easily be misinterpreted as pneumonia, an impression that is reinforced by the frequent accompaniment of low-grade fever. Respiratory viral infections increase the risk of developing HAPE, which may lead to further confusion in diagnosis.

Complications of HAPE in children often relate to underlying, sometimes undiagnosed, cardiopulmonary pathology or coexisting viral infections which potentiate the severity of pulmonary edema and pulmonary hypertension. Acute altitude exposure in such circumstances may lead to severe presentations that progress rapidly to extreme hypoxemia or cardiac failure and death. Children with trisomy 21, with or without structural cardiac anomalies, show increased susceptibility to HAPE and rapid symptom progression. Neonatal respiratory distress with pulmonary hypertension has been linked to exaggerated hypoxic pulmonary vasoreactivity in early adulthood and thereby a theoretical predisposition to HAPE. Other conditions related to pulmonary overcirculation (atrial and ventricular septal defects, patent foramen ovale, patent ductus arteriosus) small cross-sectional area of the pulmonary vascular bed (unilateral absent pulmonary artery, pulmonary hypoplasia), obstruction to pulmonary venous return (total anomalous pulmonary venous return, pulmonary vein stenosis), or left-sided obstruction (coarctation of the aorta) potentiate HAPE. Inflammatory processes, such as viral infection, predispose to HAPE and may worsen hypoxemia. Infection with respiratory syncytial virus, in particular, may trigger severe pulmonary hypertension.

**Management**

Descent with supplemental oxygen is the treatment of choice for HAPE in children. When feasible, or in the absence of medical care, rapid descent of at least 500-1,000 m usually results in rapid recovery. As with all altitude illness the magnitude of the descent is tailored to the resolution of symptoms. Oxygen and bed rest without descent can be safe and effective treatment for mild HAPE in children where careful medical observation is available. Mild HAPE in children and young adults at 3,750 m has been treated with bed rest alone, although clinical recovery may be slower compared to treatment with supplemental oxygen.

Supplemental oxygen at altitude is administered at 2-6 L/min by nasal cannula for 48-72 hr to maintain an arterial oxygen saturation of at least 90%. Increasing oxygen saturation above 90% does not result in further reduction in pulmonary artery pressure and does not accelerate edema resolution in adults. Oxygen flow can be weaned with improvement in symptoms and saturations; at flow rates below 2-4 L/min, children may be sufficiently stable and comfortable to continue treatment at home under the monitoring of family. Instructions to avoid physical exertion and exposure to cold should be given to reduce exposure to factors known to elevate pulmonary artery pressure. Most children experience complete resolution of mild HAPE within 24-72 hr of oxygen therapy when treated at altitude of symptom onset.

Pharmacotherapy for pediatric HAPE is rarely needed since oxygen and descent are so effective. In emergency situations without the options of supplemental oxygen or descent, pharmacotherapy is indicated. Nifedipine has been well studied for the treatment of adult HAPE. Extrapolated dosing for children is 0.5 mg/kg/dose given orally every 4-8 hr and titrated to response (maximum 10 mg/dose). Liquid-filled capsules of nifedipine (10 mg/0.34 mL) can be punctured to obtain doses for children less than 20 kg; sustained-release formulations cannot be broken to obtain reliable smaller doses. Patients should be monitored for hypotension during nifedipine administration. Phosphodiesterase type 5 inhibitors have been studied for HAPE prevention in adults. Although sildenafil and tadalafil have shown effectiveness in adults, there is concern around use of this class of agents in young children after the U.S. Food and Drug Administration warning against the use of sildenafil for pediatric pulmonary hypertension.

Figure 73-2 AMS and HAPE. A healthy 15 yr old male flew from Buffalo, NY, to Denver, CO, and immediately drove with his school group from the airport to a ski resort at 9,300 feet in the Rocky Mountains. The following day he felt dizzy and complained of headache. Symptoms of headache and dizziness continued along with emesis daily for 2 days. A snowboarding coach brought the patient to the local emergency facility the next day because of dyspnea, cough, headache, emesis, and fatigue. Pulse oximetry showed an arterial saturation of 51%. Chest x-ray showed diffuse pulmonary edema (A). The patient was transported to Denver (5,280 feet) by ambulance with 15 L/min oxygen via a nonrebreathing mask. Saturations improved with descent and were 94% on arrival at the Children’s Hospital Colorado emergency department. Breath sounds remained coarse and the patient was tachycardic and tachypneic. Oxygen flow was weaned to 1 L/min shortly after admission. Two days after presentation, lung exam was improved, without crackles. Repeat chest x-ray showed clearing of edema pattern (B). The patient maintained adequate saturations without supplemental oxygen and was discharged. (Courtesy of the Department of Radiology, Children’s Hospital of Colorado.)
between 1 and 17 yr of age because of an apparent increase in mortality during long-term therapy. Alveolar fluid clearance is upregulated by β-adrenergic agonists and inhaled β-agonists may successfully prevent and treat HAPE.

**SPECIAL CONSIDERATIONS**

**Reentry HAPE**

Children residing at high altitude may also experience HAPE of the type termed reentry or reascent HAPE. Reentry HAPE occurs upon reascent to the altitude of residence after a sojourn to low altitude. Although stays at low altitude as short as 24 hr may be sufficient to trigger reentry HAPE, most cases occur after several days at lower altitude. Children between 4 and 18 yr of age are much more likely to develop reentry HAPE than adults.

Reentry HAPE has a significant probability of recurrence and may justify pharmacologic prophylaxis to prevent the accumulated burden of morbidity. Acetazolamide has been used empirically based on its blunting of hypoxic pulmonary vasoconstriction in adults and the potential risk of hypotension and reflex tachycardia with nifedipine. The β₁-adrenergic agonist salmeterol has also been shown effective as prophylaxis in adults. Nifedipine may be a reasonable prophylactic option in older children and adolescents with histories of multiple episodes of HAPE.

**Symptomatic High-Altitude Pulmonary Hypertension**

Infants and young children resident at high altitude may also experience symptomatic high-altitude pulmonary hypertension, also termed subacute infantile mountain sickness. All infants, regardless of altitude of gestation and birth have thickened and muscularized interlobular and intralobular pulmonary arteries and pulmonary artery pressure that are initially near systemic. While muscular regression and fall in pulmonary artery pressure occur rapidly at sea level, infants permanently residing at high altitude demonstrate slowed regression of these characteristics through infancy and even childhood. Certain infants become symptomatic with exaggerated hypoxemia and signs of subacute pulmonary hypertension; these signs correlate with pathologic findings of right ventricular hypertrophy and dilation, increased muscularization of the pulmonary arterial bed and eventual right-sided congestive heart failure. Treatment may require relocation to a lower altitude.

**Travel With Young Infants**

Newborn infants retain some of the circulatory characteristics of recent fetal life, and these can pose a unique risk for altitude exposure. The fetal circulation has high pulmonary resistance, low pulmonary blood flow and both intra- and extra-cardiac shunts that optimize oxygenation via the placenta instead of the fetal lungs. After birth, a transition begins that closes fetal shunts and establishes normal pulmonary circulation and oxygen transport. Exposure to marked hypoxia can result in reversion to fetal shunting patterns despite the absence of a placenta. Normal infants at sea level complete these changes in 4-6 wk, though for infants born at moderate or high altitude, changes may last 3 mo or longer. Travel to high altitude with young infants is generally safe after 4-6 wk when circulatory changes have occurred, breastfeeding is established, and congenital abnormalities may have been detected.

Air travel with young infants frequently raises questions about the effects of exposure to hypobaric hypoxia, as the pressurization of aircraft cabins may vary up to an altitude equivalent of 8,500 feet (approximately 2,600 m). Transoceanic flights are generally not long enough to trigger AMS or HAE; infants may experience transient desaturation with feedings during flight and likely experience discomfort because of dry air, and stress caused by noise and vibration. Former preterm infants without chronic lung disease who have attained 3 mo corrected gestational age do not appear to experience greater hypoxemia during air travel than term infants; infants with more significant lung disease merit hypoxic challenge or provision for supplemental oxygen in flight.

**Sickle Trait/Disease**

Children with sickle cell disease or sickle trait should avoid travel to altitude, as hypoxemia may trigger sickling and painful crises, including splenic crises. Up to 20% of pediatric patients with sickle cell and sickle-thalassemia disease may experience a vasocclusive crisis at moderate altitude or in pressurized aircraft. Oxygen is advised for air travelers with known sickle cell disease. Although the majority of children with sickle trait remain asymptomatic, children can experience splenic ischemia or infarction, with severe left upper quadrant pain. Splenic infarction may be more common in nonblack patients (often of Mediterranean origin) with sickle trait.

**PREVENTION**

A comprehensive approach to travel to high altitude with children should focus on 3 phases: planning the ascent and assessment of risk, recognition and management of altitude-associated illness, and follow-up of any illness relative to future travel or diagnostic testing necessary.

Planning for travel to high altitude with children should consider rate of ascent, formulation of an emergency plan for communication and evacuation, and availability of medical care at the high-altitude destination. Slow ascent with time for acclimatization is the best prevention for all forms of altitude illness. Ideally, the first night should be spent at an altitude no higher than 2,800 m and then 2-3 nights should be spent at 2,500-3,000 m, with a subsequent increase (to a new sleeping altitude) of not more than 500 m each night. One extra night of acclimatization (at the same sleeping altitude) should be taken for every 1,000 m gained. Rapid ascent by air may be avoidable through alternate routes or alternate means of transportation. Difficult descent situations (where further ascent may be necessary before descent is possible) should be avoided with children. The availability of medical care and evacuation from altitude will influence the degree of personal preparation necessary. Widespread coverage by cellular and satellite phone service may give a false sense of security in remote regions where both terrain and weather can limit the arrival of definitive help.

Medical risk assessment encompasses consideration of age, previous altitude-associated illness, and possible predisposing circumstances to altitude illness. Very young infants (younger than 4-6 wk) may not have completed the postnatal circulatory transition and may be more vulnerable to altitude-associated desaturation with periodic breathing, right-to-left shunting across the foramen ovale, and hypoxic pulmonary vasoconstriction. Infants who required supplemental oxygen during the neonatal period, especially for pulmonary hypertension, may be at risk for hypoxemia with prolonged altitude exposure. History and physical exam are useful to identify conditions predisposing to HAPE, including recent viral infections, cardiac malformations, or obstructive sleep apnea. Low-risk children should not need medications for prophylaxis and should use gradual ascent to prevent illness.

Prompt recognition of altitude-associated illness requires awareness of the context in which illness occurs and familiarity with the signs and symptoms. Parents are generally adept at recognizing deviation from baseline behavior of their children. Clinicians should emphasize to parents that breathing difficulty, cyanosis, cough productive of pink-tinged sputum, altered mental status, or neurologic abnormalities are not part of uncomplicated AMS, but instead are serious signs of potential HAPE or HACE that deserve immediate medical attention.

Descent is the mainstay of therapy for all forms of altitude-associated illness in children. When descent is not feasible or illness is mild, other therapeutic options may be chosen. Severe altitude illness or death can be avoided in children by adherence to 3 general principles:

1. Recognition of the early signs of altitude illness and willingness by adult caregivers to acknowledge them.
2. No further ascent, especially to sleep at a higher altitude, when experiencing even minor symptoms/signs of altitude illness.
3. Immediate descent if signs/symptoms worsen while resting/receiving treatment at the altitude of onset.

Uncomplicated AMS with full resolution of symptoms upon descent or treatment does not require diagnostic work-up, but may prompt discussion of slower ascent, specific plans for treatment, or even
prophylaxis for future travel. Signs of HAPE or severe hypoxemia in a child disproportionate to the altitude reached should prompt further diagnostic evaluation, including consideration of echocardiography. Underlying cardiac conditions may not be apparent on physical examination at low altitude; cardiac echocardiography or catheterization under conditions of controlled hypoxia or hypoxic exercise may be necessary. Families of HAPE-susceptible children should be advised to avoid travel during or shortly after viral infection.

Bibliography is available at Expert Consult.
Chapter 73  ◆  Altitude-Associated Illness in Children (Acute Mountain Sickness)

Drowning is one of the leading causes of childhood morbidity and mortality in the world. Prevention is the most important step to reducing the impact of drowning injury, followed by early initiation of cardiopulmonary resuscitation (CPR) at the scene.

**ETIOLOGY**

Children are at risk of drowning when they are exposed to a water hazard in their environment. The World Congress of Drowning definition of drowning is: “Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid.” The term drowning does not imply the final outcome—death or survival; the outcome should be denoted as fatal or nonfatal drowning. Use of this terminology should improve consistency in reporting and research; the use of confusing descriptive terms such as “near,” “wet,” “dry,” “secondary,” “silent,” “passive,” and “active” should be abandoned. The injury following a drowning event is hypoxia.

**EPIDEMIOLOGY**

From 2005-2009, an average of 3,880 people per year were victims of fatal drowning and an estimated 5,789 persons were treated in U.S. hospital emergency departments (EDs) for nonfatal drowning. Compared with other types of injuries, drowning has one of the highest case fatality rates. Highest drowning death rates were seen in children ages 1-4 yr and 15-19 yr (2.55 and 1.29/100,000, respectively). In children, drowning is second only to motor vehicle injury as a leading cause of death from unintentional injury in the United States. Pediatric hospitalization rates associated with drowning ranged from 4.7 to 2.4 per 100,000 between 1993 and 2008. Rates of fatal drowning hospitalization declined from 0.5 to 0.3 deaths per 100,000 during the same period. Morbidity following nonfatal drowning is poorly studied.

The risk of drowning and the circumstances leading to it vary by age (Fig. 74-1). Drowning risk also relates to other host factors including male gender, alcohol use, a history of seizures, swimming lessons. Environmental risk factors include exposure to water and varying supervision. These factors are embedded in the context of geography, climate, socioeconomic status, and culture.

**Children Younger Than 1 Year of Age**

Most (71%) drowning deaths in children younger than 1 yr occur in the bathtub, when an infant is left alone or with an older sibling. Infant tub seats or rings may exacerbate the risk by giving caregivers a false sense of security that the child is safe in the tub. The next major risk to this age group is the large (5-gallon) household bucket, implicated in 16% of infant drowning deaths. These buckets are approximately 30 cm tall and designed to not tip over when half full. The average 9-mo-old child tends to be top-heavy, so can easily fall head first into a half-full bucket, become stuck, and drown within minutes.

**Children 1-4 Years of Age**

Drowning rates are consistently highest in 1-4 yr old children, likely because of their curious, but unaware, nature, coupled with the rapid progression of their physical capabilities. U.S. rates are highest in the southern regions; in some areas as high as 7.62/100,000, which approaches rates seen in developing countries. A common factor in many of these deaths is a lapse in adult supervision, often <5 min. Most U.S. drownings occur in residential swimming pools. Usually, the child is in the child’s own home and the caregiver does not expect the child to be anywhere near the pool.

In rural areas, children in this age group often drown in irrigation ditches or nearby ponds and rivers. The circumstances are similar to those noted previously, in a body of water that is near the house. Drowning is one of the leading causes of farm injury–related deaths in children.

**School-age Children**

School-age children are at increased risk of drowning in natural bodies of water such as lakes, ponds, rivers, and canals. Although swimming pools account for the majority of nonfatal drownings, open water accounts for a higher death rate from this age group on through adolescence. Unlike for preschool children, swimming or boating activities are important factors in drowning injuries in school-aged children.

**Adolescents**

The second major peak in drowning death rates occurs in older adolescents, age 15-19 yr. Almost 70% drown in natural freshwater. In this age group particularly, striking disparities in drowning deaths exist in gender and race. Males account for 80% of fatal drownings. The drowning rates for adolescent males are nearly 10 times higher than those for adolescent females. The gender disparity may likely be related to males’ greater risk-taking behavior, greater alcohol use, less perception about risks associated with drowning, as well as greater belief in their swimming ability than females. In 2009, as in previous years, drowning rates for black males age 15-19 yr were nearly double those for white males of the same age. Racial differences are only partially explained by socioeconomic status; other cultural factors contribute. Black children are more likely to drown in unguarded public or apartment pools, whereas white children are more likely to drown in private residential pools. Hispanic and foreign-born children have lower rates of drowning than their white counterparts. Differences in exposure to swimming lessons, cultural attitudes, and fears about swimming, as well as experience around water, may contribute to drowning risk.

**Underlying Conditions**

Several underlying medical conditions are associated with drowning at all ages. A number of studies have found an increased risk, up to 19-fold, in individuals with epilepsy. Drowning risk for children with seizures is greatest in bathtubs and swimming pools. Cardiac etiologies, including arrhythmias, myocarditis, and prolonged QT syndromes have been found in some children who die suddenly in the water (see Chapters 435.5), particularly in those with a family history of syncope, cardiac arrest, prior drowning, or QT prolongation. Some children with long QT syndrome are misdiagnosed as having seizures.

Drowning may also be an intentional injury. A history of the event that changes or is inconsistent with the child’s developmental stage is the key to recognition of intentional drowning. Physical examination and other physical injuries rarely provide clues. Child abuse is more often recognized in bathtub-related drownings. Suicide usually occurs in lone swimmers in open water.

**Alcohol Use**

The use of alcohol and drugs greatly increases the risk of drowning. Of teenagers and adults who die, 30-40% have positive blood alcohol
Part IX  The Acutely Ill Child

levels. Alcohol can impair judgment, leading to riskier behavior, decreased balance and coordination, and blunted ability to self-rescue. Furthermore, an intoxicated adult may provide less-effective supervision of children around water.

Sports and Recreation
Most drowning deaths in the United States occur during recreational activities. Drowning is the leading cause of noncardiac sports-related deaths. Surveys confirm that alcohol use is common during water recreation, as is not using a personal flotation device (PFD) during boating activities. In 2012, the United States Coast Guard reported that almost 90% of those who drowned in boating accidents in the United States were not wearing a PFD.

Global Impact of Drowning
Drowning injury is a significant problem for children worldwide, with the vast majority (96%) of fatalities occurring in low and middle income countries in Asia. Given the relative size of the pediatric population in many of these countries, drowning is one of the leading causes of death globally. A recent UNICEF study estimated that approximately 77,000 children in this region alone died from drowning between 2004 and 2008. This number vastly underestimates the global drowning rate, as many drowning deaths in this region go unreported, with 64–100% of those deaths being underreported in developing countries. Instead, significant locations for drowning in U.S. children, these are virtually unreported locations for drownings in developing countries. Instead, the predominant locations are near or around the home, involving bodies of water used for activities of daily living. These include water-collecting systems, ponds, ditches, creeks, and watering holes. In tropical areas, death rates increase during monsoon season, when ditches and holes rapidly fill with rain, and are highest during daylight hours, when caregivers are busy with daily chores.

Drowning during natural disasters such as storms and floods is important in all areas of the world. The largest numbers of reported flood-related deaths occur in developing nations; most are drownings that occur during the storm surge. In the United States and much of Europe, advances in weather monitoring and warning systems have reduced such deaths. U.S. flooding incidents, including hurricanes Katrina and Sandy, showed that drowning caused the most deaths, particularly when people became trapped in their vehicles, were unable or refused to evacuate homes, or attempted to rescue others.

PATHOPHYSIOLOGY
Drowning victims drown silently and do not signal distress or call for help. Vocalization is precluded by efforts to achieve maximal lung volume to keep the head above the water or by aspiration leading to laryngospasm. Young children can struggle for only 10–20 sec and adolescents for 30–60 sec before final submersion. A swimmer in distress is vertical in the water, pumping the arms up and down. This splashing or efforts to breathe are often misconstrued by nearby persons as merely “playing” in the water until the victim sinks.

Anoxic–Ischemic Injury
After experimental submersion, a conscious animal initially panics, trying to surface. During this stage, small amounts of water enter the hypopharynx, triggering laryngospasm. There is a progressive decrease in arterial blood oxygen saturation (SaO2), and the animal soon loses consciousness from hypoxia. Profound hypoxia and medullary depression lead to terminal apnea. At the same time, the cardiovascular response leads to progressively decreasing cardiac output and oxygen delivery to other organs. By 3–4 min, myocardial hypoxia leads to abrupt circulatory failure. Ineffective cardiac contractions with electrical activity may occur briefly, without effective perfusion (pulseless electrical activity). With early initiation of CPR, spontaneous circulation may initially be successfully restored. The extent of the global hypoxic–ischemic injury determines the final outcome and becomes more evident over subsequent hours.

With modern intensive care, the cardiorespiratory effects of resuscitated drowning victims are usually manageable and are less often the cause of death than irreversible hypoxic–ischemic central nervous system (CNS) injury (see Chapter 68). CNS injury is the most common cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury begins is uncertain, it is probably on the order of 3–5 min. Ninety percent of victims with reported submersions of less than 5 min survive and appear normal at hospital discharge.

Several hours after cardiopulmonary arrest, cerebral edema may occur, although the mechanism is not entirely clear. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; intracranial hypertension is an ominous sign of profound CNS damage.

All other organs and tissues may exhibit signs of hypoxic–ischemic injury. In the lung, damage to the pulmonary vascular endothelium can lead to acute respiratory distress syndrome (see Chapter 71). Aspiration may also compound pulmonary injury. Myocardial dysfunction (so-called stunning), arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute kidney injury, cortical necrosis, and renal failure are common complications of major hypoxic–ischemic events (see Chapter 535.1). Vascular endothelial injury may initiate disseminated intravascular coagulation, hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage; bloody diarrhea with mucosal sloughing may be seen and often portends a fatal injury. Serum levels of hepatic transaminases and pancreatic enzymes are often acutely increased. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

Pulmonary Injury
Pulmonary aspiration (see Chapter 397) occurs in a majority of drowning victims, but the amount of aspirated fluid is usually small. Aspirated water does not obstruct airways and is readily moved into the

Anoxic–Ischemic Injury
After experimental submersion, a conscious animal initially panics, trying to surface. During this stage, small amounts of water enter the hypopharynx, triggering laryngospasm. There is a progressive decrease in arterial blood oxygen saturation (SaO2), and the animal soon loses consciousness from hypoxia. Profound hypoxia and medullary depression lead to terminal apnea. At the same time, the cardiovascular response leads to progressively decreasing cardiac output and oxygen delivery to other organs. By 3–4 min, myocardial hypoxia leads to abrupt circulatory failure. Ineffective cardiac contractions with electrical activity may occur briefly, without effective perfusion (pulseless electrical activity). With early initiation of CPR, spontaneous circulation may initially be successfully restored. The extent of the global hypoxic–ischemic injury determines the final outcome and becomes more evident over subsequent hours.

With modern intensive care, the cardiorespiratory effects of resuscitated drowning victims are usually manageable and are less often the cause of death than irreversible hypoxic–ischemic central nervous system (CNS) injury (see Chapter 68). CNS injury is the most common cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury begins is uncertain, it is probably on the order of 3–5 min. Ninety percent of victims with reported submersions of less than 5 min survive and appear normal at hospital discharge.

Several hours after cardiopulmonary arrest, cerebral edema may occur, although the mechanism is not entirely clear. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; intracranial hypertension is an ominous sign of profound CNS damage.

All other organs and tissues may exhibit signs of hypoxic–ischemic injury. In the lung, damage to the pulmonary vascular endothelium can lead to acute respiratory distress syndrome (see Chapter 71). Aspiration may also compound pulmonary injury. Myocardial dysfunction (so-called stunning), arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute kidney injury, cortical necrosis, and renal failure are common complications of major hypoxic–ischemic events (see Chapter 535.1). Vascular endothelial injury may initiate disseminated intravascular coagulation, hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage; bloody diarrhea with mucosal sloughing may be seen and often portends a fatal injury. Serum levels of hepatic transaminases and pancreatic enzymes are often acutely increased. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

Pulmonary Injury
Pulmonary aspiration (see Chapter 397) occurs in a majority of drowning victims, but the amount of aspirated fluid is usually small. Aspirated water does not obstruct airways and is readily moved into the
pulmonary circulation with positive pressure ventilation. It can wash out surfactant and cause alveolar instability, ventilation-perfusion mismatch, and intrapulmonary shunting. In humans, aspiration of small amounts (1-3 mL/kg) can lead to marked hypoxemia and a 10-40% reduction in lung compliance. The composition of aspirated material can affect the patient’s clinical course: Gastric contents, pathogenic organisms, toxic chemicals, and other foreign matter can injure the lung or cause airway obstruction. Clinical management is not significantly different in saltwater and freshwater aspirations, because most victims do not aspirate enough fluid volume to make a clinical difference. A few children may have massive aspiration, increasing the likelihood of severe pulmonary dysfunction.

Cold Water Injury
Drowning should be differentiated from cold water immersion injuries, in which the victim remains afloat, keeping the head above water without respiratory impairment in cold waters. The definition of cold water varies from less than 15-20°C (59-68°F).

Heat loss through conduction and convection is more efficient in water than in air. Children are at increased risk for hypothermia because of their relatively high ratio of body surface area to mass, decreased subcutaneous fat, and limited thermogenic capacity. Hypothermia can develop as a result of prolonged surface contact with cold water during immersion, while the airway is above water, or with submersion. Body temperature may also continue to fall as a result of cold air, wet clothes, hypoxia, and hospital transport. Hypothermia in pediatric drowning victims may be observed even after drowning in relatively warm water and in warm climates.

Immersion in cold water has immediate respiratory and cardiovascular effects. Victims experience cold water shock, a dynamic series of cardiorespiratory physiologic responses that can cause drowning. In adults, immersion in icy water results in intense involuntary reflex hyperventilation and to a decrease in breath-holding ability to <10 sec, which leads to fluid aspiration. Severe bradycardia, the diving reflex, occurs in adults but is transient and rapidly followed by supraventricular and ectopic tachycardia and hypertension. There is no evidence that the diving reflex has any protective effect.

Even after surviving the chaotic minutes of cold water shock, after an additional 5-10 min of cold water immersion, the victim can become incapacitated. Cooling of large and small muscles disables the victim’s ability to grab hold, swim or perform other self-rescue maneuvers. Depending on water and air temperature, insulation, body surface area, thermogenic capacity, physical condition, swimming efforts, or high water flow rates, heat loss with continued immersion can significantly decrease core temperature to hypothermic levels within 30-60 min.

The symptoms and severity of hypothermia are categorized based on body temperature. The victim with mild hypothermia has a temperature of 34-36°C (93.2-96.8°F) with intact thermogenic mechanisms (shivering and nonshivering thermogenesis, vasoconstriction) and active movements. Compensatory mechanisms usually attempt to restore normothermia at body temperatures >32°C (89.6°F). Lower core temperatures lead to impaired cognition, coordination, and muscle strength and with it, less ability to self-rescue. Thermoregulation may fail and spontaneous rewarming will not occur. With moderate hypothermia (30 to <34°C [86 to <93.2°F]), loss of consciousness leads to water aspiration. Progressive bradycardia, impaired myocardial contractility, and loss of vasomotor tone contribute to inadequate perfusion, hypotension, and possible shock. At body temperatures <28°C (82.4°F), extreme bradycardia is usually present with decreases in cardiac output, and the propensity for spontaneous ventricular fibrillation or asystole is high. Central respiratory center depression with moderate to severe hypothermia results in hypoventilation and eventual apnea. A deep coma, with fixed and dilated pupils and absence of reflexes at very low body temperatures (<25-29°C [77-84.2°F]), may give the false appearance of death.

The brain can cool to a neuroprotective level if the cooling process is quick and cardiac output lasts long enough for sufficient heat loss to occur prior to the onset of severe hypoxia. However, if submersion leading to drowning occurs prior to development of a neuroprotective level of hypothermia, severe anoxia devastates tissue organs. The theoretical benefits, implications, and consequences of hypothermia in drowning victims are areas of controversy. Known adverse effects are associated with hypothermia, and these must be balanced against the potential benefits observed in experimental data. One should clearly differentiate among (a) controlled hypothermia, such as that used in the operating room before the onset of hypoxia or ischemia, (b) accidental hypothermia, such as occurs in drowning, which is uncontrolled and variable with onset during or shortly after hypoxia–ischemia, and (c) therapeutic hypothermia, involving the purposeful and controlled lowering and maintenance of body (or brain) temperature at some time after a hypoxic–ischemic event.

In drowning victims with uncontrolled accidental hypothermia associated with icy water submersion, there are a few case reports of good neurologic recovery after prolonged (10-150 min) cardiopulmonary arrest. Almost all of these rare survivors have been in freezing water (<5°C [41°F]) and had core body temperatures <30°C (86°F), often much lower. Presumably, very rapid and sufficiently deep hypothermia developed in these fortunate survivors before irreversible hypoxic–ischemic injury occurred.

Most often hypothermia is a poor prognostic sign, and a neuroprotective effect has not been demonstrated. In King County, Washington, where the water is cold but rarely icy, 92% of drowning survivors with good neurologic outcomes had initial body temperatures ≥34°C (93.2°F), whereas 61% of those who died or had severe neurologic injury had temperatures <34°C (93.2°F). In another study of comatose drowning patients admitted to pediatric intensive care units (PICUs), 65% of hypothermic patients (body temperature <35°C [95°F]) died, compared with a 27% observed mortality rate in nonhypothermic victims. Similarly, in Finland (where the median water temperature was 16°C [60.9°F]) and in the United States, a beneficial effect of drowning-associated hypothermia was not seen in pediatric submersion victims; submersion duration <10 min was most strongly related to good outcome, not water temperature.

MANAGEMENT
The clinical course and outcome for a submersion victim are primarily determined by the duration of submersion, the speed of the rescue, and the effectiveness of resuscitative efforts. Two groups may be identified on the basis of responsiveness at the scene. The first group consists of children who require minimal resuscitation at the scene and quickly regain spontaneous respiration and consciousness. They have good outcomes and minimal complications. These victims should be transported from the scene to the ED for further evaluation and observation.

The second group comprises children in cardiac arrest who require aggressive or prolonged resuscitation and have a high risk of multiorgan system complications, major neurologic morbidity, or death. Compared with cardiac arrest from other causes, cardiac arrest from drowning has a higher survival rate.

Initial management of drowning victims requires coordinated and experienced prehospital care following the ABCs (airway, breathing, circulation) of emergency resuscitation (see Chapter 67). Cardiopulmonary resuscitation of drowning victims must include providing ventilation. Children with severe hypoxic injury and symptoms often remain comatose and lack brainstem reflexes despite the restoration of oxygenation and circulation. Subsequent ED and PICU care often involve advanced life support strategies and management of multiorgan dysfunction.

Initial Evaluation and Resuscitation
See Chapter 67.

Once a submersion has occurred, immediate institution of CPR efforts at the scene is imperative. The goal is to reverse the anoxia from submersion and limit secondary hypoxic injury after submersion. Every minute that passes without the reestablishment of adequate
breathing and circulation dramatically decreases the possibility of a good outcome. When safe for the victim and the rescuer, institution of in-water resuscitation for nonbreathing victims by trained personnel may improve the likelihood of survival. Victims usually need to be extricated from the water as quickly as possible so that effective CPR can be provided. Common themes in children who have good recovery are a short duration of event and initiation of CPR as soon as possible, prior to arrival of emergency medical services.

**Initial resuscitation must focus on rapidly restoring oxygenation, ventilation, and adequate circulation.** The airway should be clear of vomitus and foreign material, which may cause obstruction or aspiration. Abdominal thrusts should not be used for fluid removal, because many victims have a distended abdomen from swallowed water; abdominal thrusts may increase the risk of regurgitation and aspiration. In cases of suspected airway foreign body, chest compressions or back blows are preferable maneuvers.

The cervical spine should be protected in anyone with potential traumatic neck injury (see Chapters 68 and 72). Cervical spine injury is a rare concomitant injury in drowning; only approximately 0.5% of submersion victims have cervical spine injuries. History of the event and victim age guide suspicion of cervical spine injury. Drowning victims with cervical spine injury are usually preteens or teenagers whose drowning event involved diving, a motorized vehicle crash, a fall from a height, a water sport accident, child abuse, or other clinical signs of serious traumatic injury. In such cases, the neck should be maintained in a neutral position and protected with a well-fitting cervical collar. Patients rescued from unknown circumstances may also warrant cervical spine precautions. In low-injury severity submersion, spinal injuries are exceedingly rare, and routine spinal immobilization is not warranted.

If the victim has ineffective respiration or apnea, ventilatory support must be initiated immediately (see Chapter 67). Mouth-to-mouth or mouth-to-nose breathing by trained bystanders often restores spontaneous ventilation. As soon as it is available, supplemental oxygen should be administered to all victims. Positive-pressure bag-mask ventilation with 100% inspired oxygen should be instituted in patients with respiratory insufficiency. If apnea, cyanosis, hypoventilation, or labored respiration persists, trained personnel should perform endotracheal tube intubation as soon as possible. Intubation is also indicated to protect the airway in patients with depressed mental status or hemodynamic instability. Hypoxia must be corrected rapidly to optimize the chance of recovery.

Concurrent with securing of airway control, oxygenation, and ventilation, the child's cardiovascular status must be evaluated and treated according to the usual resuscitation guidelines and protocols. Heart rate and rhythm, blood pressure, temperature, and end-organ perfusion require urgent assessment. CPR should be instituted immediately in pulseless, bradycardic, or severely hypotensive victims. Continuous monitoring of the electrocardiogram (ECG) allows appropriate diagnosis and treatment of arrhythmias. Slow capillary refill, cool extremities, and altered mental status are potential indicators of shock (see Chapter 70).

Recognition and treatment of hypothermia are the unique aspects of cardiac resuscitation in the drowning victim.** (Table 74-1). Core temperature must be evaluated, especially in children, because moderate to severe hypothermia can depress myocardial function and cause arrhythmias. Wet clothing should be removed to prevent ongoing heat losses, however, in the hemodynamically stable patient, rewarming should be initiated in the controlled environment of the receiving ED or PICU. Unstable patients (i.e. arrhythmias) should be warmed to 34°C (93.2°F), taking care not to overheat. Trials are investigating if therapeutic hypothermia might be helpful or if avoiding hyperthermia is actually the key element to long-term neurologic survival.

Often, IV fluids and cardiovascular medications are required to improve circulation and perfusion. Vascular access should be established as quickly as possible for the administration of fluids or pressors. Intravenous catheter placement is a potentially lifesaving vascular access technique that avoids the delay usually associated with multiple attempts to establish IV access in critically ill children. Epinephrine is usually the initial drug of choice in victims with bradycystolic cardiopulmonary arrest (the IV dose is 0.01 mg/kg of 1:10,000 solution given q3-5min as needed). Epinephrine can be given intratracheally (endotracheal tube dose is 0.1-0.2 mg/kg of 1:1,000 solution) if no IV access is available. An intravascular bolus of lactated Ringer solution or 0.9% normal saline (10-20 mL/kg) is often used to augment preload; repeated doses may be necessary. Hypotonic or glucose-containing solutions should not be used for intravascular volume administration of drowning victims.

**Hospital-Based Evaluation and Treatment**

Most pediatric drowning victims should be observed for at least 6-8 hr, even if they are asymptomatic on presentation to the ED. At a minimum, serial monitoring of vital signs (respiratory rate, heart rate, blood pressure, and temperature) and of oxygenation by pulse oximetry, and neurologic assessment should be performed in all drowning victims. Other studies may also be warranted, depending on the specific circumstances (possible abuse or neglect, traumatic injuries, or suspected intoxication). Almost half of asymptomatic or minimally symptomatic alert children (those who do not require advanced life support in the prehospital setting or who have an initial ED Glasgow Coma Scale [GCS] score of ≥13) experience some level of respiratory distress or hypoxemia progressing to pulmonary edema, usually during the 1st 4-8 hr after submersion. Most alert children with early respiratory symptoms respond to oxygen and, despite abnormal initial radiographs, become asymptomatic with a return of normal room air SaO₂ and pulmonary examination by 4-6 hr. Subsequent delayed respiratory deterioration is extremely unlikely in such children. Selected low-risk patients who are alert and asymptomatic with normal physical findings and oxygenation levels may be considered for discharge after 6-8 hr of observation, as long as appropriate follow-up can be ensured.

**Cardiorespiratory Management**

For children who are not in cardiac arrest, the level of respiratory support should be appropriate to the patient's condition and is a continuation of prehospital management. Frequent assessments are required to ensure that adequate oxygenation, ventilation, and airway control are maintained (see Chapter 71). Hypercapnia should generally be avoided in potentially brain-injured children. Patients with actual or potential hyperventilation or markedly elevated work of breathing should receive mechanical ventilation to avoid hypercapnia and decrease the energy expenditures of labored respiration.

Measures to stabilize cardiovascular status should also continue. Conditions contributing to myocardial insufficiency include hypoxic-ischemic injury, ongoing hypoxia, hypothermia, acidosis, high airway pressures during mechanical ventilation, alterations of intravascular volume, and electrolyte disorders. Heart failure, shock, arrhythmias, or cardiac arrest may occur. Continuous ECG monitoring is mandatory for recognition and treatment of arrhythmias (see Chapter 435).

The provision of adequate oxygenation and ventilation is a prerequisite to improving myocardial function. Fluid resuscitation and inotropic agents are often necessary to improve heart function and restore tissue perfusion (see Chapter 67). Increasing preload with IV fluids may be beneficial through improvements in stroke volume and cardiac output. Overzealous fluid administration, especially in the presence of poor myocardial function, can worsen pulmonary edema.

For patients with persistent cardiopulmonary arrest on arrival in the ED after non-icy water drowning, the decision to withhold or stop resuscitative efforts can be addressed by review of the history and the response to treatment. Because there are reports of good outcome following ongoing CPR in the ED, most drowning victims should be treated aggressively upon presentation. However, for children who do not show ready response to aggressive resuscitative efforts, the need for prolonged ongoing CPR after non-icy water submersion almost invariably predicts death or persistent vegetative state. Consequently, in most cases, discontinuation of CPR in the ED is probably warranted.
for victims of non–icy water submersion who do not respond to resuscitation within 25-30 min. Final decisions regarding whether and when to discontinue resuscitative efforts must be individualized, with the understanding that the possibility of good outcome is generally very low with protracted resuscitation efforts.

**Neurologic Management**

Drowning victims who present to the hospital awake and alert usually have normal neurologic outcomes. In comatose victims, irreversible CNS injury is highly likely. The most critical and effective neurologic intensive care measures after drowning are rapid restoration and maintenance of adequate oxygenation, ventilation, and perfusion. Core body temperature and glucose management may also be important modulators of neurologic injury after hypoxia–ischemia.

Comatose drowning patients are at risk for intracranial hypertension. There is little evidence that ICP monitoring and therapy to reduce intracranial hypertension improve outcomes for drowning victims. Patients with elevated ICP usually have poor outcomes—either death or persistent vegetative state. Children with normal ICP can also have poor outcomes, although less frequently. Conventional neurologic intensive care therapies, such as fluid restriction, hyperventilation, and administration of muscle relaxants, osmotic agents, diuretics, barbiturates, and steroids, have not been shown to benefit the drowning victim, either individually or in combination. There is some evidence that these therapies may reduce overall mortality but increase the number of survivors with severe neurologic morbidity.

Electroencephalographic monitoring has only limited value in the management of drowning victims and is generally not recommended, except to detect seizures or as an adjunct in the clinical evaluation of brain death (see Chapter 68.1). Seizures should be treated if possible, although they tend to be very refractory. There is no evidence that treatment of seizures after drowning improves outcome. Fosphenytoin or phenytoin (loading dose of 10-20 mg of phenytoin equivalents/kg, followed by maintenance dosing with 5-8 mg of phenytoin equivalents/kg/day in 2-3 divided doses; levels should be monitored) may be considered as an anticonvulsant; it may have some neuroprotective effects and may mitigate neurogenic pulmonary edema. Benzodiazepines, barbiturates, and other anticonvulsants may also have some role in seizure therapy.

With optimal management, many initially comatose children can have impressive neurologic improvement, but usually do so within the 1st 24-72 hr. Unfortunately, almost half of deeply comatose drowning victims admitted to the PICU die of their hypoxic brain injury or survive with severe neurologic damage. Many children become brain dead. Deeply comatose drowning victims who do not show substantial improvement on neurologic examination after 24-72 hr and whose coma cannot be otherwise explained should be seriously considered for limitation or withdrawal of support.

**Other Management Issues**

A few drowning victims may have traumatic injury (see Chapter 72), especially if their drowning event involved participation in high energy water sports such as personal watercraft, boating, diving, or surfing. A high index of suspicion for such injury is required. Spinal precautions should be maintained in victims with altered mental status and suspected traumatic injury. Significant anemia suggests trauma and internal hemorrhage.

Hyperoxic–ischemic injury can have multiple systemic effects, although protracted organ dysfunction is uncommon in the absence of severe CNS injury. Hyperglycemia is associated with a poor outcome in pediatric drowning victims. Its etiology is unclear but it is possibly a stress response.

Manifestations of acute kidney injury may be seen after hypoxic–ischemic injury (see Chapter 535). Diuretics, fluid restriction, and dialysis are occasionally needed to treat fluid overload or electrolyte disturbances; renal function usually normalizes in survivors. Rhabdomyolysis after drowning has been reported.

Profuse bloody diarrhea and mucosal sloughing usually portend a grim prognosis; conservative management includes bowel rest, nasogastric suction, and gastric pH neutralization. Nutritional support for most drowning victims is usually not difficult, because the majority of children either die or recover quickly and resume a normal diet within a few days; enteral tube feeding or parenteral nutrition is occasionally indicated in children who do not recover quickly.

Hyperthermia after drowning or other types of brain injury may increase the risk of mortality and exacerbate hypoxic–ischemic CNS damage. Almost half of drowning victims have a fever during the 1st 48 hr after submersion. Hyperthermia is usually not caused by

**Chapter 74 – Drowning and Submersion Injury**

---
infection and resolves without antibiotics in approximately 80% of patients. Generally, prophylactic antibiotics are not recommended. However, there is general consensus that fever or hyperthermia (core body temperature >37.5°C [99.5°F]) in comatose drowning victims resuscitated from cardiac arrest should be prevented at all times in the acute recovery period (at least the 1st 24-48 hr).

Psychiatric and psychosocial sequelae in the family of a pediatric drowning victim are common. Grief, guilt, and anger are common among family members, including siblings. Divorce rates of up to 80% within a few years of the injury have been reported, and parents often report difficulties with employment or substance abuse. Friends and family may blame the parents for the event. Professional counseling, pastoral care, or social work referral should be initiated for drowning victims and their families.

Hypothermia Management

Attention to core body temperature starts in the field and continues during transport and in the hospital. The goal is to prevent or treat moderate or severe hypothermia. Damp clothing should be removed from all drowning victims. Rewarming measures are generally categorized as passive, active external, or active internal (see Chapter 76). Passive rewarming measures can be applied in the prehospital or hospital setting; they include the provision of dry blankets, a warm environment, and protection from further heat loss. They should be instituted as soon as possible for hypothermic drowning victims who have not had a cardiac arrest.

Full CPR with chest compressions is indicated for hypothermic victims if no pulse can be found or if narrow complex QRS activity is absent on ECG (see Chapters 67 and 76). When core body temperature is <30°C (86°F), resuscitative efforts should proceed according to the current American Heart Association guidelines for CPR, but IV medications may be given at a lower frequency in moderate hypothermia because of decreased drug clearance. When ventricular fibrillation is present in severely hypothermic victims (core temperature <30°C [86°F]), defibrillation should be initiated but may not be effective until the core temperature is ≥30°C (86°F), at which time successful defibrillation may be more likely.

Significant controversy surrounds the discontinuation of prolonged resuscitative efforts in hypothermic drowning victims. Body temperature should be taken into account before resuscitative efforts are terminated. Other considerations include whether the victim may have been immersed prior to submersion, whether water was icy or the cooling was very rapid with fast-flowing cold water. Victims with profound hypothermia may appear clinically dead, but full neurologic recovery is possible, although rare. Attempts at lifesaving resuscitation should not be withheld on the basis of initial clinical presentation unless the victim is obviously dead (dependent lividity or rigor mortis). Rewarming efforts should usually be continued until the temperature is 32-34°C (89.6-93.2°F); if the victim continues to have no effective cardiac rhythm and remains unresponsive to aggressive CPR, then resuscitative efforts may be discontinued.

Complete rewarming is not indicated for all arrest victims before resuscitative efforts are abandoned. Discontinuing resuscitation in victims of non-icy water submersion who remain asyptic despite 30 min of CPR is probably warranted. Physicians must use their individual clinical judgment about deciding to stop resuscitative efforts, taking into account the unique circumstances of each incident.

Once a drowning victim has undergone successful CPR after a cardiac arrest, temperature management should be carefully considered, and body temperature should be continuously monitored. In victims in whom resuscitation duration was brief and who are awake soon after resuscitation, attempts to restore and maintain normothermia are warranted. Careful monitoring is necessary to prevent unrecognized worsening hypothermia, which can have untoward consequences.

For drowning victims who remain comatose after successful CPR, more contentious issues include rewarming of hypothermic victims and controlled application of therapeutic hypothermia. Although there is no evidence basis or consensus of opinion, many investigators cautiously recommend that hypothermic drowning victims who remain unresponsive because of hypoxic-ischemic encephalopathy after restoration of adequate spontaneous circulation should not be actively rewarmed to normal body temperatures. Active rewarming should be limited to victims with core body temperatures <32°C (89.6°F), but temperatures 32-37.5°C (89.6-99.5°F) should be allowed without further rewarming efforts.

More controversial is the induction of therapeutic hypothermia in drowning victims who remain comatose because of hypoxic-ischemic encephalopathy after CPR for cardiac arrest. The 2002 World Congress on Drowning recommended that hypothermia (32-34°C [89.6-93.2°F]) be instituted as soon as possible after resuscitation and sustained for 12-24 hr. They recommended that patients be intubated, mechanically ventilated, and treated with sedatives and/or analgesics (with or without neuromuscular blocking agents) as necessary to prevent shivering and maintain hypothermia then gradually rewarmed.

However, a specific recommendation for therapeutic hypothermia, especially in children, is not yet generally accepted. The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation (2002) did not recommend therapeutic hypothermia in drowned children resuscitated after cardiopulmonary arrest, citing insufficient evidence and older studies demonstrating a potential deleterious effect in pediatric drowning victims. Several subsequent studies evaluating extracorporeal membrane circulation, rewarming, and therapeutic hypothermia in pediatric and adult drowned patients have shown no significant improvement in neurologic outcome or mortality rates.

PROGNOSIS

The outcomes for drowning victims are remarkably bimodal: The great majority of victims either have a good outcome (intact or mild neurologic sequelae) or a bad outcome (severe neurologic sequelae, persistent vegetative state or death), with very few exhibiting intermediate neurologic injury at hospital discharge. Subsequent evaluation of good outcome survivors may identify significant persistent cognitive deficits. Of hospitalized pediatric drowning victims, 15% die and as many as 20% survive with severe permanent neurologic damage.

Strong predictors of outcome are based on the incident and response to treatment at the scene. Intact survival or mild neurologic impairment has been seen in 91% of children with submersion duration ≤5 min and in 87% with resuscitation duration ≤10 min. Children with normal sinus rhythm, reactive pupils, or neurologic responsiveness at the scene virtually always had good outcomes (99%). Poor outcome is highly likely in patients with deep coma, apnea, absence of papillary responses, and hyperglycemia in the ED, with submersion durations ≥10 min, and with failure of response to CPR given for ≥25 min. In one comprehensive case series, all children with resuscitation durations ≥25 min either died or had severe neurologic morbidity, and all victims with submersion durations ≥25 min died.

Long-term health-related quality of life and school performance in subjects who had received either bystander or emergency medical service personnel initiated CPR was high if their submersion duration was <10 mins. Higher morbidity, mortality, and lower quality of life was reported in those patients with >10 mins submersion durations. In several studies of pediatric drowning, submersion duration was the best predictor of outcome and water temperature was not. However, there are rare case reports of intact recovery following non-icy water drowning with longer submersion or resuscitation duration.

The GCS score has some limited utility in predicting recovery. Children with a score ≥6 on hospital admission generally have a good outcome, whereas those with a score ≤5 have a much higher probability of poor neurologic outcome. Occasionally, children with a GCS score of 3 or 4 in the ED have complete recovery. Improvement in the GCS score during the first several hours of hospitalization may indicate a better prognosis. Overall, early GCS assessments fail to adequately
distinguish children who will survive intact from those with major neurologic injury.

Neurologic examination and progression during the 1st 24-72 hr are the best prognosticators of long-term CNS outcome. Children who regain consciousness within 48-72 hr, even after prolonged resuscitation, are unlikely to have serious neurologic sequelae. In a small series of comatose victims of non–icy water submersion, all survivors with a good outcome had spontaneous purposeful movements and normal brainstem function within 24 hr; good recovery did not occur in any child with abnormal brainstem function or absence of purposeful movements at 24 hr. In another small series of drowning victims who remained unconscious >24 hr and survived for at least 1 yr, 73% remained in a persistent vegetative state and the rest had severe neurologic impairment, had many complications and a high mortality rate: 45% died during the study’s 1-yr follow-up period.

In a large retrospective series of 274 pediatric drowning victims, of those with an initial GCS score of 3 in the ED, only 14% survived intact. Almost all, 95%, of victims who demonstrated purposeful neurologic function within 48 hr survived intact and 100% of those whose first purposeful neurologic response occurred within 6 hr survived intact. Laboratory and technologic methods to improve prognostication have not yet proved superior to neurologic examination. Serial neurologic evaluations after CPR should be performed over the ensuing 48-72 hr, with consideration given to limitation or withdrawal of support in patients who do not have significant neurologic recovery, even though this may occur before absolute prognostic certainty is achieved.

**PREVENTION**

The most effective way to decrease the injury burden of drowning is prevention. Drowning is a multifaceted problem, but several evidence-based preventive strategies are effective. The pediatrician has a prime opportunity to identify and inform families at risk of these strategies through anticipatory guidance. In 2010, the American Academy of Pediatrics Committee on Injury, Violence, and Poison Prevention revised its policy statement on the prevention of drowning to advocate for more anticipatory guidance regarding the appropriate supervision of children, access to swim lessons, the presence of lifeguards, barriers to swimming pools, and use of PFDs. A family-centered approach to anticipatory guidance for water safety helps explore and identify the water hazards that each family is exposed to in their environment. The practitioner can then discuss the best tools and strategies for prevention that are relevant for the particular family. It is important to identify the risks both in and around the home and in other locations they may frequent, often when vacationing, such as vacation or relatives’ homes. For some families the focus may be on bathtubs and bucket safety; for others, home pools or hot tubs may be the major hazards. If the family recreates near or on open water, they also need to learn about safety around boats and open water. In a rural environment, water collection systems and natural bodies of water may pose great risk.

Parents must build layers of water protection around their children. **Table 74-1** provides an approach to the hazards and preventive strategies relevant to the most common sources of water involved in childhood drowning. A common preventive strategy for exposure to all water types and all ages is ensuring appropriate supervision. Pediatricians should define for parents what constitutes appropriate supervision at the various developmental levels of childhood. Many parents either underestimate the importance of adequate supervision or are simply unaware of the risks associated with water. Even parents who say that constant supervision is necessary will often admit to brief lapses while their child is alone near water. Parents also overestimate the abilities of older siblings; many bathtub drownings occur when an infant or toddler is left with a child younger than 5 yr.

Supervision of infants and young children means that a responsible adult should be with the child every moment. The caregiver must be alert, must not be consuming alcohol or other drugs or socializing, and must be attentive and focused entirely on watching the child. Even a brief moment of inattention, such as to answer a phone, get a drink, or hold a conversation, can have tragic consequences. If the child does not swim, “touch supervision” is required, meaning that the caregiver should be within arm’s reach at all times. Adolescents require active adult supervision and avoidance of alcohol or drug use during water activities. Learning to swim offers another layer of protection. Children may start swim lessons at an early age that are developmentally appropriate and aimed at the individual child’s readiness and skill level. Swim lessons are beneficial and to provide some level of protection to young children. A study from Bangladesh, where drowning accounts for 20% of all deaths in children ages 1-4 yr, showed that swim lessons and water safety curricula are cost-effective and led to a decrease in mortality from drowning. As with any other water safety intervention, parents need to know that swimming lessons and acquisition of swim skills cannot be solely relied on to prevent drowning. No child can be “drown-proof.” A supervising caretaker should be aware of where and how to get help and know how to safely rescue a child in trouble. Because only those trained in water rescue can safely attempt it, families should be encouraged to swim in designated areas only when and where a lifeguard is on duty.

Children and adolescents should never swim alone regardless of their swimming abilities. Even as they become more independent and participate in recreational activities without their parents, they should be encouraged to seek areas that are watched by lifeguards. Lifeguards rescue more than 100,000 Americans each year from drowning, and probably prevent millions more drownings through verbal warnings and prompt interventions when needed. It is important to emphasize that even if the child is considered a strong swimmer, the ability to swim in a pool does not translate to being safe in open water, where water temperature, currents, and underwater obstacles can present additional and unfamiliar challenges. For swimmers, supervision by lifeguards reduces drowning risk, because lifeguards monitor risk behaviors and are trained in the difficult and potentially dangerous task of rescuing drowning victims.

Two of the preventive strategies listed in **Table 74-1** deserve special mention. The most vigorously evaluated and effective drowning intervention applies to swimming pools. Isolation fencing that completely surrounds a pool, with a secure, self-locking gate, reduces the risk of drowning. Guidelines for appropriate fencing, provided by the U.S. Consumer Product Safety Commission, are very specific; they were developed through testing of active toddlers in a gymnastics program on their ability to climb barriers of different materials and heights and recent studies show them to be effective in preventing drowning in young children. In families who have a pool on their property, caregivers often erroneously believe that if a child falls into the water there will be a loud noise or splash to alert them. Sadly, these events are usually silent, delaying timely rescue. This finding highlights the need for a fence that actually separates the pool from the house, not just surrounds the entire property. The use of U.S. Coast Guard–approved lifejackets or PFDs should be advised with all families spending time around open water, not just those who consider themselves boaters. This issue is also particularly important for families who will participate in aquatic activities on a vacation. A PFD should be chosen with respect to the weight of the child and the proposed activity. Young children should wear PFDs that will float their head up. Parents should be urged to wear PFDs, too, as their use is associated with greater use by their children. Toys such as water wings and “floaties” should not be relied upon as drowning prevention measures.

Effective preventive efforts must also consider cultural practices. Different ethnic groups may have certain attitudes, beliefs, dress, or other customs that may affect their water safety. The higher drowning risk of minority children needs to be addressed by community-based prevention programs. In addition to anticipatory guidance, pediatricians can play an active role in drowning prevention by participating in advocacy efforts to
improve legislation for pool fencing, PFD use, and alcohol consumption in various water activities. Several counties in the United States, Australia, and New Zealand have laws requiring isolation fencing for pools. Their effectiveness has been limited by a lack of enforcement. Similarly, all states have boating-under-the-influence laws but, similarly, rarely enforce them. Furthermore, efforts at the community level may be needed to ensure the availability of swimming lessons for underserved populations and lifeguarded swim areas.

Chapter 74 ♦ Drowning and Submersion Injury  568.e1

Bibliography

Burns are a leading cause of unintentional injury in children, second only to motor vehicle crashes. There has been a decline in the incidence of burn injury requiring medical care that has coincided with a stronger focus on burn treatment and prevention, increased fire and burn prevention education, greater availability of regional treatment centers, widespread use of smoke detectors, greater regulation of consumer products and occupational safety, and societal changes such as reductions in smoking and alcohol abuse.

EPIDEMIOLOGY

Approximately 2 million people in the United States require medical care for burn injuries each year. Approximately 50% of these patients are younger than age 5 yr, with an average age of 32 mo. The principal cause of the burn is scald; one of the causes of scald burn is heating liquids in the microwave. The leading cause of burn in children 5-14 yr of age is flame injury. In children ages 5-10 yr, this is usually a result of match play, whereas, for older children, it is usually a result of gasoline ignition. Fires are a major cause of mortality in children, accounting for up to 34% of fatal injuries in those younger than age 16 yr. Scald burns account for 85% of total injuries and are most prevalent in children younger than 4 yr. Although the incidence of hot water scalding has been reduced by legislation requiring new water heaters to be preset at 48.9°C (120°F), scald injury remains the leading cause of hospitalization for burns. Steam inhalation used as a home remedy to treat respiratory infections is another potential cause of burns. Flame burns account for 13%; the remaining are electrical and chemical burns. Clothing ignition events have declined since passage of the Federal Flammable Fabric Act requiring sleepwear to be flame-retardant; however, the U.S. Consumer Product Safety Commission has voted to relax the existing children’s sleepwear flammability standard. Polyester is the fabric most resistant to ignition by small flame source. Polyester does burn deeply as it melts, but it self-extinguishes when the flame source is removed. Cotton, on the other hand, continues to burn after the flame source has been removed resulting in large deep burns. Polyester melts downward, sparing the face and respiratory tract; cotton burns upward toward the face. Pellet stove, glass front stoves, and flat top stoves are becoming frequent sources of hand burns in children. Approximately 18% of burns are the result of child abuse (usually scalds), making it important to assess the pattern and site of injury and their consistency with the patient history (see Chapter 40). Friction burns from treadmills are also a problem. Hands are the most commonly injured sites, with deep 2nd-degree friction injury sometimes associated with fractures of the fingers. Anoxia, not the actual burn, is a major cause of morbidity and mortality in house fires.

Review of the history usually shows a common pattern: scal burns to the side of the face, neck, and arm if liquid is pulled from a table or stove; burns in the pant leg area if clothing ignites; burns in a splash pattern from cooking; and burns on the palm of the hand from contact with a hot stove. However, “glove or stocking” burns of the hands and feet, single-area deep burns on the trunk, buttocks, or back, and small, full-thickness burns (cigarette burns) in young children should raise the suspicion of child abuse (see Chapter 40).

Burn care involves a range of activities: prevention, acute care and resuscitation, wound management, pain relief, reconstruction, rehabilitation, and psychosocial adjustment. Children with massive burns require early and appropriate psychological and social support as well as resuscitation. Surgical debridement, wound closure, and rehabilitative efforts should be instituted concurrently to promote optimal rehabilitation. Aggressive surgical removal of devitalized tissue, infection control, and judicious use of antibiotics, as well as early nutrition and cautious use of intubation and mechanical ventilation, are necessary to maximize survival. Children who have sustained burn injuries differ in appearance from their peers, necessitating supportive efforts for reentry to school and social and sporting activities.

PREVENTION

The aim of burn prevention is a continuing reduction in the number of serious burn injuries (Table 75-1). Effective first aid and triage can decrease both the extent (area) and the severity (depth) of injuries. The use of flame-retardant clothing and smoke detectors, control of hot water temperature (thermostat settings) to 48.9°C (120°F) within buildings, and prohibition of cigarette smoking have been partially successful in reducing the incidence of burn injuries. Treatment of children with significant burn injuries in dedicated burn centers facilitates medically effective care, improves survival, and leads to greater cost efficiency. Survival of at least 80% of patients with burns of 90% of the body surface area (BSA) is possible; the overall survival rate of children with burns of all sizes is 99%. Death is more likely in children with irreversible anoxic brain injury sustained at the time of the burn. It is well-known that burns occur in predictable patterns. Seasonal pattern sources include:

Winter
- Glass front fireplaces/pellet stoves and radiators increase hand burns
- Treadmill injuries as more people exercise inside—child imitates adults or young child touches belt

Summer
- Fireworks, sparkler—temperatures reach 537.8°C (1000°F)
- Burn contact with hot grill; hand/feet burn from hot embers
- Lawnmowers

Spring/Fall
- Burning leaves
- Gasoline burns
- Tap water scalds are essentially preventable through a combination of behavioral and environmental changes

Pediatricians can play a major role in preventing the most common burns by educating parents and healthcare providers. Simple, effective, efficient, and cost-effective preventive measures include the use of appropriate clothing and smoke detectors, and the planning of routes for emergency exit from the home. The National Fire Protection Association (NFPA) recommends replacing smoke detector batteries annually and the smoke detector alarm every 10 yr (or earlier, if indicated on the device). Child neglect and abuse must be seriously considered when the history of the injury and the distribution of the burn do not match.

ACUTE CARE, RESUSCITATION, AND ASSESSMENT

Indications for Admission

Burns covering >10% of total BSA, burns associated with smoke inhalation, burns resulting from high-tension (voltage) electrical injuries,
Burn Prophylaxis

**PREVENT FIRES**
Install and use smoke detectors
Control the hot water thermostat—in public buildings, the maximum water temperature should be 48.9°C (120°F)
Keep fire, matches, and lighters out of the reach of children
Avoid cigarette smoking, especially in bed
Do not leave lit candles unattended
Use flame retardant–treated clothing
Use caution when cooking, especially with oil
Keep cloth items off heaters

**PREVENT INJURY**
Roll, but do not run, if clothing catches fire; wrap in a blanket
Practice escape procedures
Crawl beneath smoke if a fire occurs indoors
Use educational materials*

**First Aid Measures**

Acute care should include the following measures:

1. Extinguish flames by rolling the child on the ground; cover the child with a blanket, coat, or carpet.
2. After determining that the airway is patent, remove smoldering clothing or clothing saturated with hot liquid. Jewelry, particularly rings and bracelets, should be removed or cut away to prevent constriction and vascular compromise during the edema phase in the 1st 24-72 hr after burn injury.
3. In cases of chemical injury, brush off any remaining chemical, if powdered or solid; then use copious irrigation or wash the affected area with water. Call the local poison control center for the neutralizing agent to treat a chemical ingestion.
4. Cover the burned area with clean, dry sheeting and apply cold (not iced) wet compresses to small injuries. Significant large-burn injury (>15% of BSA) decreases body temperature control and contraindicates the use of cold compresses.
5. If the burn is caused by hot tar, use mineral oil to remove the tar.
6. Administer analgesic medications.

---

**Table 75-3** Acute Treatment of Burns

| First aid, including washing of wounds and removal of devitalized tissue |
|--------------------------|----------------------|
| Fluid resuscitation | Provision of energy requirements |
| Life-support measures | Control of pain |
| Prevention of infection—early excision and grafting | Prevention of excessive metabolic expenditures |
| Control of bacterial wound flora | Use of biologic and synthetic dressings to close the wound |

**Emergency Care**

Life-support measures are as follows (Table 75-3):

1. Rapidly review the cardiovascular and pulmonary status and document pre-existing or physiologic lesions (asthma, congenital heart disease, renal or hepatic disease).
2. Ensure and maintain an adequate airway and provide humidified oxygen by mask or endotracheal intubation (Fig. 75-1). The latter may be needed in children who have facial burns or a burn sustained in an enclosed space, before facial or laryngeal edema becomes evident. If hypoxia or carbon monoxide poisoning is suspected, 100% oxygen should be used (see Chapters 67 and 71).
3. Children with burns >15% of BSA require intravenous (IV) fluid resuscitation to maintain adequate perfusion. In an emergency situation if IV access is unattainable, an intraosseous line should be placed. When inserting central lines to provide high-volume fluid, special attention should be paid to use a very-small-caliber catheter in small children to avoid injury to the vascular lining, which may predispose to formation of clots. All inhalation injuries, regardless of the extent of BSA burn, require venous access to control fluid intake. All high-tension and electrical injuries require venous access to ensure forced alkaline diuresis in case of muscle injury to avoid myoglobinuric renal damage. Lactated Ringer solution, 10-20 mL/kg/hr (normal saline may be used if lactated Ringer solution is not available), is initially infused until proper fluid replacement can be calculated. Consultation with a specialized burn unit should be made to coordinate fluid therapy, the type of fluid, the preferred formula for calculation, and preferences for the use of colloid agents, particularly if transfer to a burn center is anticipated.
4. Evaluate the child for associated injuries, which are common in patients with a history of high-tension electrical burn, especially if there has also been a fall from a height. Injuries to the spine, bones, and thoracic or intraabdominal organs may occur (see Chapter 72). Cervical spine precautions should be observed until this injury is ruled out. There is a very high risk of cardiac abnormalities, including ventricular tachycardia and ventricular fibrillation, resulting from conductivity of the high electric voltage. Cardiopulmonary resuscitation should be instituted promptly at the scene, and cardiac monitoring should be started upon the patient’s arrival at the emergency department (see Chapter 67).
5. Children with burns of >15% of BSA should not receive oral fluids (initially), because gastric distention may develop. These children require insertion of a nasogastric tube in the emergency department to prevent aspiration. A Foley catheter should be inserted to monitor urine output in all children who require IV fluid resuscitation.
6. All wounds should be wrapped with sterile dressings until a decision is made about whether to treat the patient on an outpatient basis or refer the patient to an appropriate facility for treatment.
7. A carbon monoxide measurement (carboxyhemoglobin [HbCO]) should be obtained for fire victims, and 100% oxygen administered until the result is known.

Classification of Burns

Proper triage and treatment of burn injury require assessment of the extent and depth of the injury (Table 75-4 and Fig. 75-2). First-degree burns involve only the epidermis and are characterized by swelling, erythema, and pain (similar to mild sunburn). Tissue damage is usually minimal, and there is no blistering. Pain resolves in 48-72 hr; in a small percentage of patients, the damaged epithelium peels off, leaving no residual scars.

A 2nd-degree burn involves injury to the entire epidermis and a variable portion of the dermal layer (vesicle and blister formation are characteristic). A superficial 2nd-degree burn is extremely painful because a large number of remaining viable nerve endings are exposed. Superficial 2nd-degree burns heal in 7-14 days as the epithelium regenerates in the absence of infection. Midlevel to deep 2nd-degree burns also heal spontaneously if wounds are kept clean and infection-free. Pain is less than in more superficial burns because fewer nerve endings remain viable. Fluid losses and metabolic effects of deep dermal (2nd-degree) burns are essentially the same as those of 3rd-degree burns.

Full-thickness, or 3rd-degree, burns involve destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the damaged area. The wound cannot epithelialize and can heal only by wound contraction or skin grafting. The absence of painful sensation and capillary filling demonstrates the loss of nerve

Figure 75-1 Algorithm for the primary survey of a major burn injury. O₂, oxygen. (From Hettiaratchy S, Papini R: Initial management of a major burn I: overview. BMJ 328:1555-1557, 2004.)
and capillary elements. The use of Doppler scanner has become a valuable adjunct tool in burn depth assessment and burn healing potential.

**Estimation of Body Surface Area for a Burn**

Appropriate burn charts for different childhood age groups should be used to accurately estimate the extent of BSA burned. The volume of fluid needed in resuscitation is calculated from the estimation of the extent and depth of burn surface. Mortality and morbidity also depend on the extent and depth of the burn. The variable growth rate of the head and extremities throughout childhood makes it necessary to use BSA charts, such as that modified by Lund and Brower or the chart used at the Shriners Hospital for Children in Boston (Fig. 75-3). The rule of nines used in adults may be used only in children older than 14 yr or as a very rough estimate to institute therapy before transfer to a burn center. In small burns, <10% of BSA, the rule of palm may be used, especially in outpatient settings: The area from the wrist crease to the finger crease (the palm) in the child equals 1% of the child's BSA.

**TREATMENT**

**Outpatient Management of Minor Burns**

A patient with 1st- and 2nd-degree burns of <10% of BSA may be treated on an outpatient basis unless family support is judged inadequate or there are issues of child neglect or abuse. These outpatients do not require a tetanus booster (unless not fully immunized) or prophylactic penicillin therapy. Blisters should be left intact and dressed with bacitracin ointment and left open. Debridement of the devitalized skin is indicated when the blisters rupture. A variety of wound dressings/wound membranes are available (e.g., AQUACEL Ag dressing [Convatec USA, Skillman, NJ] in a soft felt-like material impregnated with silver ion) may be applied to 2nd-degree burns and wrapped with a dry sterile dressing; similar wound membranes provide pain control, prevention of wound desiccation, and reduction in wound colonization (Table 75-5). These dressings are usually kept on for 7-10 days but are checked twice a week.

Burns to the palm with large blisters usually heal beneath the blisters; they should receive close follow-up on an outpatient basis. The great majority of superficial burns heal in 10-20 days. Deep 2nd-degree burns take longer to heal and may benefit from enzymatic debridement ointment application (collagenase ointment) applied daily on the wound, which aids in the removal of the dead tissue. These ointments should not be applied to the face to avoid the risk of getting them into the eyes.

The depth of scald injuries is difficult to assess early; conservative treatment is appropriate initially, with the depth of the area involved

Fluid Resuscitation

Fluid resuscitation should begin soon after the injury has occurred, in the emergency department before transferring to a burn center. For most children, the Parkland formula is an appropriate starting guideline for fluid resuscitation (4 mL lactated Ringer solution/kg/% BSA burned). Half of the fluid is given over the 1st 8 hr, calculated from the time of onset of injury; the remaining fluid is given at an even rate over the next 16 hr. The rate of infusion is adjusted according to the patient’s response to therapy. Pulse and blood pressure should return to normal, and an adequate urine output (>1 mL/kg/hr in children; 0.5-1.0 mL/kg/hr in adolescents) should be accomplished by varying the IV infusion rate. Vital signs, acid–base balance, and mental status reflect the adequacy of resuscitation. Because of interstitial edema and sequestration of fluid in muscle cells, patients may gain up to 20% over baseline (preburn) body weight. Patients with burns of 30% of BSA require a large venous access (central venous line) to deliver the fluid required over the critical 1st 24 hr. Patients with burns of >60% of BSA may require a multilumen central venous catheter; these patients are best cared for in a specialized burn unit. In addition to fluid resuscitation, children should receive standard maintenance fluids (see Chapter 36).

During the 2nd 24 hr after the burn, patients begin to reabsorb edema fluid and to experience diuresis. Half of the 1st day’s fluid requirement is infused as lactated Ringer solution in 5% dextrose. Children younger than 5 yr may require the addition of 5% dextrose in the 1st 24 hr of resuscitation. Controversy exists as to whether colloid should be provided in the early period of burn resuscitation. One preference is to use colloid replacement concurrently if the burn is >85% of total BSA. Colloid is usually instituted 8-24 hr after the burn injury. In children younger than 12 mo, sodium tolerance is limited; the volume and sodium concentration of the resuscitation solution should be decreased if the urinary sodium level is rising. The adequacy of resuscitation should be constantly assessed by means of vital signs as well as urine output, blood gas, hematocrit, and serum protein measurements. Some patients require arterial and central venous lines, particularly those undergoing multiple excision and grafting procedures, as needed, for monitoring and replacement purposes. Central venous pressure monitoring may be indicated to assess circulation in patients with hemodynamic or cardiopulmonary instability. Femoral vein cannulation is a safe access for fluid resuscitation, especially in infants and children. Burn patients who require frequent blood gas monitoring benefit from radial or femoral arterial catheterization.

Oral supplementation may start as early as 48 hr after burn. Milk formula, artificial feedings, homogenized milk, or soy-based products can be given by bolus or constant infusion through a nasogastric or small bowel feeding tube. As oral fluids are tolerated, IV fluids are decreased proportionately in an effort to keep the total fluid intake constant, particularly if pulmonary dysfunction is present.

A 5% albumin infusion may be used to maintain the serum albumin levels at a desired 2 g/dL. The following rates are effective: for burns of 30-50% of total BSA, 0.3 mL of 3% albumin/kg/% BSA burn is infused over 24 hr; for burns of 50-70% of total BSA, 0.4 mL/kg/% BSA burn is infused over 24 hr; and for burns of 70-100% of total BSA, 0.5 mL/kg/% BSA burn is infused over 24 hr. Infusion of packed red blood cells is recommended if the hematocrit falls to <24% (hemoglobin = 8 g/dL). Some authorities recommend treatment for hematocrit <30% or hemoglobin <10 g/dL in patients with systemic infection, hemoglobinopathy, cardiopulmonary disease, anticipated (or ongoing) blood loss, and if repeated excision and grafting of full-thickness burns are needed. Fresh-frozen plasma is indicated if clinical and laboratory assessment shows a deficiency of clotting factors, a prothrombin level >1.5 times control, or a partial thromboplastin time >1.2 times control in children who are bleeding or are scheduled for an invasive procedure or a grafting procedure that could result in an estimated blood loss of more than half of blood volume. Fresh-frozen plasma may be used for volume resuscitation within 72 hr of injury in patients younger than 2 yr with burns over 20% of BSA and associated inhalation injury.

Sodium supplementation may be required for children with burns of >20% of BSA if 0.5% silver nitrate solution is used as the topical antibacterial burn dressing. Sodium losses with silver nitrate therapy are regularly as high as 350 mmol/m² burn surface area. Oral sodium chloride supplementation of 4 g/m² burn area/24 hr is usually well tolerated, divided into 4-6 equal doses to avoid osmotic diarrhea. The aim is to maintain serum sodium levels >130 mEq/L and urinary sodium concentration >30 mEq/L. Young children under 5 yr of age are especially susceptible to hyponatremia and cerebral edema. IV potassium supplementation is supplied to maintain a serum potassium level >3 mEq/L. Potassium losses may be significantly increased when 0.5% silver nitrate solution is used as the topical antibacterial agent or when amnoglycoside, diuretic, or amphotericin therapy is required.

Prevention of Infection and Surgical Management of the Burn Wound

Controversy exists over the prophylactic use of penicillin for all patients hospitalized with acute burn injury and the periodic replacement of central venous catheters to prevent infection. In some units, a 5-day course of penicillin therapy is used for all patients with acute burns; standard-dose crystalline penicillin is given orally or intravenously in 4 divided doses. Erythromycin may be used as an alternative in penicillin-allergic children. Other units have discontinued prophylactic use of penicillin therapy without an increase in the infection rate. Similarly, there is conflicting evidence as to whether relocation of the IV catheter every 48-72 hr decreases or increases the incidence of catheter-related sepsis. Some recommend that the central venous catheter be replaced and relocated every 5-7 days, even if the site is not inflamed and there is no suspicion of catheter-related sepsis.

Mortality related to burn injury is associated not with the toxic effect of thermally injured skin, but with the metabolic and bacterial consequences of a large open wound, reduction of the patient’s host resistance, and malnutrition. These abnormalities set the stage for life-threatening bacterial infection originating from the burn wound. Wound treatment and prevention of wound infection also promote early healing and improve aesthetic and functional outcomes. Topical treatment of the burn wound with 0.5% silver nitrate solution, silver sulfadiazine cream, or mafenide acetate (Sulfamylon) cream or topical solution at a concentration of 2.5-3% to be used for wounds with multidrug-resistant bacteria aims at prevention of infection (Table 75-6). These 3 agents have tissue-penetrating capacity. Regardless of the choice of topical antimicrobial agent, it is essential that all 3rd-degree burn tissue be fully excised before bacterial colonization occurs and that the area is grafted as early as possible to prevent deep wound sepsis. Children with a burn of >30% of BSA should be housed in a bacteria-controlled nursing unit to prevent cross-contamination.
than in adolescents and adults. Providing environmental temperatures large surface area not controlled; this is especially true in young infants, in whom the caused by cold stress if environmental humidity and temperature are 50-100% higher than predicted for their age. Early excision and grafting time lapse since the burn, children with a burn of 40% of total BSA characterized by both protein and fat catabolism. Depending on the burn injury produces a hypermetabolic response is a high priority. The burn injury produces a hypermetabolic response of 0.1-0.2 mg/kg/day given orally, to promote better protein synthesis while the nutritional support by nasogastric feeding and IV hyperalimentation continues.

**Topical Therapy**

Topical therapy is widely used and is effective against most burn wound pathogens (see Table 75-6). A number of topical agents are used: 0.5% silver nitrate solution, sulfacetamide acetate cream or solution, silver sulfdiazine cream, and Accuzyme ointment or AQUACEL Ag®. Accuzyme is an enzymatic debridement agent and may cause a stinging feeling for 15 min after application. Preferences vary among burn units. Each topical agent has advantages and disadvantages in application, comfort, and bacteriostatic spectrum. Mafenide acetate is a very effective broad-spectrum agent with the ability to diffuse through the burn eschar; it is the treatment of choice for injury to cartilaginous surface, such as the ear; mafenide acetate solution at a concentration of 5% is useful for the treatment of burn wounds that are heavily colonized with multidrug–resistant bacteria (use should be limited to 5 days). The carbonic anhydrase inhibition activity of mafenide acetate may cause acid–base imbalance if large surface areas are treated, and adverse reactions to the sulfur-containing agents may produce transient leukopenia. This latter reaction is mostly noted with the use of silver sulfadiazine cream when applied over large surface areas in children younger than 5 yr of age. This phenomenon is transient, self-limiting, and reversible. No sulfa-containing agent should be used if the child has a history of sulfa allergies.

**Nutritional Support**

Supporting the increased energy requirements of a patient with a burn is a high priority. The burn injury produces a hypermetabolic response characterized by both protein and fat catabolism. Depending on the time lapse since the burn, children with a burn of 40% of total BSA require basal energy expenditure (oxygen consumption) approximately 50-100% higher than predicted for their age. Early excision and grafting can decrease the energy requirement. Pain, anxiety, and immobilization increase the physiologic demands. Additional energy expenditure is caused by cold stress if environmental humidity and temperature are not controlled; this is especially true in young infants, in whom the large surface area:mass ratio allows proportionately greater heat loss than in adolescents and adults. Providing environmental temperatures of 28-33°C (82.4-91.4°F), adequate covering during transport and and to provide a temperature- and humidity-controlled environment to minimize hypermetabolism.

Deep 2nd-degree burns of >10% of BSA benefit from early excision and grafting. To improve outcome, sequential excision and grafting of 3rd-degree and deep 2nd-degree burns is required in children with large burns. Prompt excision with immediate wound closure is achieved with autografts, which are often meshed to increase the efficiency of coverings. Alternatives for wound closure, such as allografts, xenografts, and Integra (Integra LifeSciences, York, PA) and other synthetic skin coverings (bilaminate membrane composed of a porous lattice of crosslinked chondroitin-6-sulfate engineered to induce neovascularization as it is biodegraded), may be important for wound coverage in patients with extensive injury to limit fluid, electrolyte, and protein losses and to reduce pain and minimize temperature loss. Epidermal cultured cells (autologous keratinocytes) are a costly alternative and are not always successful. An experienced burn team can safely perform early-stage or total excision while burn fluid resuscitation continues. Important keys to success are: (1) accurate preoperative and intraoperative determination of burn depth, (2) the choice of excision area and appropriate timing, (3) control of intraoperative blood loss, (4) specific instrumentation,(5) the choice and use of perioperative antibiotics, and (6) the type of wound coverage chosen. This process can accomplish early wound coverage without the use of recombinant human growth hormone.

**Inhalational Injury**

Inhalational injury is serious in the infant and child, particularly if preexisting pulmonary conditions are present (see Chapter 71). Inhalation injury should be suspected in a patient confined to a closed space (building), with a history of an explosion or a decreased level of consciousness, or with evidence of carbon deposits in the oropharynx or nose, singed facial hair and carbonaceous sputum. Mortality estimates vary, depending on the criteria for diagnosis, but are 45-60% in adults; exact figures are not available in children. Evaluation aims at early identification of inhalation airway injuries. These may occur from (1) direct heat (greater problems with steam burns), (2) acute asphyxia, (3) carbon monoxide poisoning, and (4) toxic fumes, including cyanides from combustible plastics. Sulfur and nitrogen oxides and alkalis...
formed during the combustion of synthetic fabrics produce corrosive chemicals that may erode mucosa and cause significant tissue sloughing. Exposure to smoke may cause degradation of surfactant and decrease its production, resulting in atelectasis. Inhalation injury and burn injury are synergistic, and the combined effect can increase morbidity and mortality.

The pulmonary complications of burns and inhalation can be divided into 3 syndromes that have distinct clinical manifestations and temporal patterns:

1. Early complications include carbon monoxide poisoning, airway obstruction, and pulmonary edema. Inhalation injury should be assessed from the evidence of obvious injury (swelling or carbonaceous material in the nasal passages), wheezing, crackles or poor air entry, and laboratory determinations of (HbCO) and arterial blood gases.

   Treatment is initially focused on establishing and maintaining a patent airway through prompt and early nasotracheal or orotracheal intubation and adequate ventilation and oxygenation. Wheezing is common, and β-agonist aerosols or inhaled corticosteroids are useful. Aggressive pulmonary toilet and chest physiotherapy are necessary in patients with prolonged nasotracheal intubation or in the rare patient with a tracheotomy. An endotracheal tube can be maintained for months without the need for tracheostomy. If tracheostomy must be performed, it should be delayed until burns at and near the site have healed, and then it should be performed electively, with the child under anesthesia and the use of optimal tracheal positioning and hemostasis. In children with inhalation injury or burns of the face and neck, upper airway obstruction can develop rapidly; endotracheal intubation becomes a lifesaving intervention. Extubation should be delayed until the patient meets the accepted criteria for maintaining the airway.

   Signs of CNS injury from hypoxemia caused by asphyxia or carbon monoxide poisoning vary from irritability to depression. Carbon monoxide poisoning may be mild (<20% HbCO), with slight dyspnea, headache, nausea, and decreased visual acuity and higher cerebral functions; moderate (20-40% HbCO), with irritability, agitation, nausea, dimness of vision, impaired judgment, and rapid fatigue; or severe (40-60% HbCO), producing confusion, hallucination, ataxia, collapse, acidosis, and coma. Measurement of HbCO is important for diagnosis and treatment. The PaO2 value may be normal and the HbCO saturation values misleading because HbCO is not detected by the usual tests of oxygen saturation. Carbon monoxide poisoning is assumed until the tests are performed, and it is treated with 100% oxygen. Significant carbon monoxide poisoning requires hyperbaric oxygen therapy (see Chapter 63).

   Patients with severe inhalation injury or with other causes of respiratory deterioration that lead to acute respiratory distress syndrome who do not improve with conventional pressure-controlled ventilation (progressive oxygenation failure, as manifested by oxygen saturation <90% while receiving FIO2 of 0.9-1.0 and positive end-expiratory pressure of at least 12.5 cm H2O) may benefit from high-frequency ventilation or nitric oxide inhalation treatment. Nitric oxide usually is administered through the ventilator at 5 parts per million (ppm) and increased to 30 ppm. This method of therapy reduces the need for extracorporeal membrane oxygenation.

**Pain Relief and Psychologic Adjustment**

See Chapter 62.

It is important to provide adequate analgesia, anxiolytics, and psychologic support to reduce early metabolic stress, decrease the potential for posttraumatic stress syndrome, and allow future stabilization as well as physical and psychologic rehabilitation. Patients and family members require team support to work through the grieving process and accept long-term changes in appearance.

Children with burn injury show frequent and wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn; the stage of healing; the patient’s age and stage of emotional development and cognition; the experience and efficiency of the treating team; the use of analgesics and other drugs; the patient’s pain threshold; and interpersonal and cultural factors. From the onset of treatment, preemptive pain control during dressing changes is of paramount importance. The use of a variety of nonpharmacologic interventions as well as pharmacologic agents must be reviewed throughout the treatment period. Opiate analgesia, prescribed in an adequate dose and timed to cover dressing changes, is essential to comfort management. A supportive person who is consistently present and “knows” the patient profile can integrate and encourage patient participation in burn care. The problem of undermedication is most prevalent in adolescents, in whom fear of drug dependence may inappropriately influence treatment. A related problem is that the child’s specific pain experience may be misinterpreted; for anxious patients, those who are confused and alone, or those with preexisting emotional disorders, even small wounds may illicit intense pain. Anxiolytic medication added to the analgesic is usually helpful and has more than a synergistic effect. Equal attention is necessary to decrease stress in the intubated patient. Other modalities of pain and anxiety relief (relaxation techniques) can decrease the physiologic stress response. Oral morphine sulfate (immediate release) is recommended at a consistent schedule at a dose of 0.3-0.6 mg/kg every 4-6 hr initially and until wound cover is accomplished. Morphine sulfate IV bolus at a dose of 0.05-0.1 mg/kg maximum of 2.5 mg every 2 hr is administered. Morphine sulfate rectal suppositories may be useful at a dose of 0.3-0.6 mg/kg every 4 hr when oral administration is not possible. The use of codeine preparation should be limited to children older than age 6 yr because of the “ultrapapid metabolizers” of codeine into morphine. For anxiety, lorazepam is given on a consistent schedule, 0.05-0.1 mg/kg/dose every 6-8 hr. To control pain during a procedure (dressing change or debride-ment), oral morphine at a dose of 0.3-0.6 mg/kg is given 1-2 hr before the procedure and this is supplemented by a morphine IV bolus at a dose of 0.05-0.1 mg/kg given immediately before the procedure. Lorazepam at a dose of 0.04 mg/kg is given orally or intravenously, if necessary, for anxiety before the procedure. Midazolam (Versed) is also very useful for conscious sedation given at a dose of 0.01-0.02 mg/kg for nonintubated patients and 0.05-0.1 mg/kg for intubated patients, as an intravenous infusion or bolus, and may be repeated in 10 min. During the process of weaning from analgesics, the dose of oral opiates is reduced by 25% over 1-3 days, sometimes with the addition of acetaminophen as opiates are tapered. Antianxiety medications are tapered by reducing the dose of benzo diazepines at 25-50% per dose daily over 1-3 days.

For ventilated patients, pain control is accomplished by using morphine sulfate intermittently as an IV bolus at a dose of 0.05-0.1 mg/kg every 2 hr. Doses may need to be increased gradually, and some children may need continuous infusion; a starting dose of 0.05 mg/kg/hr given as an infusion is increased gradually as the need of the child changes. Naloxone is rarely needed but should be immediately available to reverse the effect of morphine, if necessary; if needed for an airway crisis, it should be given in a dose of 0.1 mg/kg up to a total of 2 mg, either intramuscularly or intravenously. For patients undergoing assisted respiration who require treatment of anxiety, midazolam is used as an intermittent IV bolus (0.04 mg/kg given by slow push every 4-6 hr) or as a continuous infusion. For intubated patients, opiates do not need to be discontinued during the process of weaning from the ventilator. Benzodiazepine should be reduced to approximately half the dose over 24-72 hr before extubation; too-rapid weaning from a benzodiazepine can lead to seizures.

There is a growing use of psychotropic medication in the care of children with burns, including prescription of selective serotonin reuptake inhibitors as antidepressants, the use of haloperidol as a neuroleptic in the critical care setting, and the treatment of post-traumatic stress disorder with benzodiazepines. Conscious sedation utilizing ketamine or propofol may be used for major dressing changes.
Reconstruction and Rehabilitation
To ensure maximum cosmetic and functional outcome, occupational and physical therapy must begin on the day of admission, continue throughout hospitalization, and, for some patients, continue after discharge. Physical rehabilitation involves body and limb positioning, splinting, exercises (active and passive movement), assistance with activities of daily living, and gradual ambulation. These measures maintain adequate joint and muscle activity with as normal a range of movement as possible after healing or reconstruction. Pressure therapy is necessary to reduce hypertrophic scar formation; a variety of prefabricated and custom-made garments are available for use in different body areas for prevention of hypertrophic scarring. These custom-made garments deliver consistent pressure on scarred areas; they shorten the time of scar maturation and decrease the thickness of the scar, the redness, and the associated itching. Continued adjustments to scarred areas (scar release, grafting, rearrangement) and multiple minor cosmetic surgical procedures are necessary to optimize long-term function and improve appearance. Replacement of areas of alopecia and scarring has been achieved with the use of tissue expander techniques. The use of ultrapulse laser for reduction of scarring is an adjunct in scar management.

School Reentry and Long-Term Outcome
It is best for the child to return to school immediately after discharge. Occasionally, a child may need to attend a few half-days (because of rehabilitation needs). It is important for the child to return to the child’s normal routine of attending school and being with peers. Planning for a return to home and school often requires a school reentry program that is individualized to each child’s needs. For a school-age child, planning for the return to school occurs simultaneously with planning for discharge. The hospital schoolteacher contacts the local school and plans the program with the school faculty, nurses, social workers, recreational/child-life therapists, and rehabilitation therapists. This team should work with students and staff to ease anxiety, answer questions, and provide information. Burns and scars evoke fears in those who are not familiar with this type of injury and can result in a tendency to withdraw from or reject the burned child. A school reentry program should be appropriate to a child’s development and changing educational needs.

Major advances have made it possible to save the lives of children with massive burns; whereas some children have had lingering physical difficulties, most have a satisfactory quality of life. The comprehensive burn care that includes experienced multidisciplinary aftercare plays an important role in recovery. Table 75-7 lists the long-term complications of burns.

**SPECIAL SITUATIONS**

**Electrical Burns**
There are 3 types of electrical burns. Minor electrical burns usually occur as a result of hitting on an extension cord. These injuries produce localized burns to the mouth, which usually involve the portions of the upper and lower lips that come in contact with the extension cord. The injury may involve or spare the corners of the mouth. Because these are nonconductive injuries (do not extend beyond the site of injury), hospital admission is not necessary and care is focused on the area of the injury visible in the mouth, it is low voltage, does not cause entry or exit wounds, or cardiac issues. Treatment with topical antibiotic creams is sufficient until the patient is seen in a burn unit outpatient department or by a plastic surgeon.

A more serious category of electrical burn is the high-tension electrical wire burn, for which children must be admitted for observation, regardless of the extent of the surface area burn. Deep muscle injury is typical and cannot be readily assessed initially. These injuries result from high voltage (>1,000 V) and occur particularly at high-voltage installations, such as electric power stations or railroads; children climb an electric pole and touch an electric box out of curiosity or accidentally touch a high-tension electric wire. Such injuries have a mortality rate of 3-15% for children who arrive at the hospital for treatment. Survivors have a high rate of morbidity, including major limb amputations. Points of entry of current through the skin and the exit site show characteristic features consistent with current density and heat. The majority of entrance wounds involve the upper extremity, with small exit wounds in the lower extremity. The electrical path, from entrance to exit, takes the shortest distance between the 2 points and may produce injury in any organ or tissue in the path of the current. Multiple exit wounds in some patients attest to the possibility of several electrical pathways in the body, placing virtually any structure in the body at risk (Table 75-8). Damage to the abdominal viscera, thoracic structures, and the nervous system (confusion, coma, paralysis) in areas remote from obvious extremity injury occurs and must be sought, particularly in injuries with multiple current pathways or those in which the victim falls from a high pole. Sometimes an ignition occurs and results in concurrent flame burn and clothing fire. Cardiac abnormalities, manifested as ventricular fibrillation or cardiac arrest, are common; patients with high-tension electrical injury need an initial electrocardiogram and cardiac monitoring until they are stable and have been fully assessed. Higher-risk patients have abnormal electrocardiographic findings and a history of loss of consciousness. Renal damage from deep muscle necrosis and subsequent myoglobinuria is another complication; such patients need forced alkaline diuresis to minimize renal damage. Soft-tissue (muscle) injury of an extremity may produce a compartment syndrome. Aggressive removal of all dead

and devitalized tissue, even with the risk of functional loss, remains the key to effective management of the electrically damaged extremity. Early debridement facilitates early closure of the wound. Damaged major vessels must be isolated and buried in a viable muscle to prevent exposure. Survival depends on immediate intensive care, whereas a functional result depends on long-term care and delayed reconstructive surgery.

Lightning burns occur when a high-voltage current directly strikes a person (most dangerous) or when the current strikes the ground or an adjacent (in-contact) object. A step voltage burn is observed when lightning strikes the ground and travels up one leg and down the other (the path of least resistance). Lightning burns depend on the current path, the type of clothing worn, the presence of metal, and cutaneous moisture. Entry, exit, and path lesions are possible; the prognosis is poorest for lesions of the head or legs. Internal organ injury along the path is common and does not relate to the severity of the cutaneous burn. Linear burns, usually 1st- or 2nd-degree, are in the locations where sweat is present. Feathering or an arborescent pattern is characteristic of lightning injury. Lightning may ignite clothing or produce serious cutaneous burns from heated metal in the clothing. Internal complications of lightning burns include cardiac arrest caused by asystole, transient hypertension, premature ventricular contractions, ventricular fibrillation, and myocardial ischemia. Most severe cardiac complications resolve if the patient is supported with cardiopulmonary resuscitation (see Chapter 67). CNS complications include cerebral edema, hemorrhage, seizures, mood changes, depression, and paralysis of the lower extremities. Rhabdomyolysis and myoglobinuria (with possible renal failure) also occur. Ocular manifestations include vitreous hemorrhage, iridocyclitis, retinal tearing or retinal detachment.

The involvement of children and youth in snowmobiling, mountain climbing, winter hiking, and skiing places them at risk for cold injury. Cold injury may produce either local tissue damage, with the injury pattern depending on exposure to damp cold (frostnip, immersion foot, or trench foot), dry cold (which leads to local frostbite), or generalized systemic effects (hypothermia).

**PATHOPHYSIOLOGY**

Ice crystals may form between or within cells, interfering with the sodium pump, and may lead to rupture of cell membranes. Further damage may result from clumping of red blood cells or platelets, causing microembolism or thrombosis. Blood may be shunted away from an affected area by secondary neurovascular responses to the cold injury; this shunting often further damages an injured part while improving perfusion of other tissues. The spectrum of injury ranges from mild to severe and reflects the result of structural and functional disturbance in small blood vessels, nerves, and skin.

**ETIOLOGY**

Body heat may be lost by conduction (wet clothing, contact with metal or other solid conducting objects), convection (wind chill), evaporation, or radiation. Susceptibility to cold injury may be increased by dehydration, alcohol or drug use, impaired consciousness, exhaustion, hunger, anemia, impaired circulation as a consequence of cardiovascular disease, and sepsis; it is also greater in very young or older persons. Certain medications may contribute to hypothermia, while others may display reduced metabolism or clearance during hypothermia (Table 76-1).

Hypothermia occurs when the body can no longer sustain normal core temperature by physiologic mechanisms, such as vasocostriction, shivering, muscle contraction, and nonshivering thermogenesis. When shivering ceases, the body is unable to maintain its core temperature; when the body core temperature falls to <35°C (95°F), the syndrome of hypothermia occurs. Wind chill, wet or inadequate clothing, and other factors increase local injury and may cause dangerous hypothermia, even in the presence of an ambient temperature that is not <17-20°C (50-60°F).

**CLINICAL MANIFESTATIONS**

**Frostnip**

Frostnip results in the presence of firm, cold, white areas on the face, ears, or extremities. Blistering and peeling may occur over the next 24-72 hr, occasionally leaving mildly increased hypersensitivity to cold for some days or weeks. Treatment consists of warming the area with an unaffected hand or a warm object before the lesion reaches a stage for some days or weeks. Treatment consists of warming the damaged area. It is important not to cause further damage by attempting to rub the area with ice or snow. The area may be warmed against an unaffected hand, the abdomen, or an axilla during transfer of the patient to a facility where more rapid warming with a warm (not hot) water bath is possible. If the skin becomes painful and swelling occurs, antiinflammatory agents are helpful and an analgesic agent is necessary. Freeze and rethaw cycles are most likely to cause permanent tissue injury, and it may be necessary to delay definitive warming and apply only mild measures if the patient is required to walk on the damaged feet en route to definitive treatment. In the hospital, the affected area should be immersed in warm water (approximately 42°C [107.6°F]), with care taken not to burn the anesthetized skin. Broken vesicles may be debrided, but intact vesicles should be left alone. Vasodilating agents, such as prazosin and phenoxybenzamine, may be helpful. Use of anticoagulants (heparin, dextran) has had equivocal results; results of chemical and surgical sympathectomy have also been equivocal. Oxygen is of help only at high altitudes. Meticulous local care, prevention of infection, and keeping the rewarmed area dry, open, and sterile provide optimal results. Recovery can be complete, and prolonged observation with conservative therapy is justified before any excision or amputation of tissue is considered. Analgesia and maintenance of good nutrition are necessary throughout the prolonged waiting period.

**Immersion Foot (Trench Foot)**

Immersion foot occurs in cold weather when the feet remain in damp or wet, poorly ventilated boots. The feet become cold, numb, pale, edematous, and clammy. Tissue maceration and infection are likely, and prolonged autonomic disturbance is common. This autonomic disturbance leads to increased sweating, pain, and hypersensitivity to temperature changes, which may persist for years. Treatment includes drying the foot, gentle rewarming and nonsteroidal antiinflammatory drugs for pain. Prevention consists of using well-fitting, insulated, waterproof, nonconstricting footwear. Once damage has occurred, patients must choose clothing and footwear that are more appropriate, dry, and well-fitting. The disturbance in skin integrity is managed by keeping the affected area dry and well-ventilated and by preventing or treating infection. Only supportive measures are possible for control of autonomic symptoms.

**Frostbite**

With frostbite, initial stinging or aching of the skin progresses to cold, hard, white anesthetic and numb areas. Clear or hemorrhagic vesicles may develop over the exposed areas. On rewarming, the area becomes blotchy, itchy, and often red, swollen, and painful. The injury spectrum ranges from complete normality to extensive tissue damage, even gangrene, if early relief is not obtained.

Treatment consists of warming the damaged area. It is important not to cause further damage by attempting to rub the area with ice or snow. The area may be warmed against an unaffected hand, the abdomen, or an axilla during transfer of the patient to a facility where more rapid warming with a warm (not hot) water bath is possible. If the skin becomes painful and swelling occurs, antiinflammatory agents are helpful and an analgesic agent is necessary. Freeze and rethaw cycles are most likely to cause permanent tissue injury, and it may be necessary to delay definitive warming and apply only mild measures if the patient is required to walk on the damaged feet en route to definitive treatment. In the hospital, the affected area should be immersed in warm water (approximately 42°C [107.6°F]), with care taken not to burn the anesthetized skin. Broken vesicles may be debrided, but intact vesicles should be left alone. Vasodilating agents, such as prazosin and phenoxybenzamine, may be helpful. Use of anticoagulants (heparin, dextran) has had equivocal results; results of chemical and surgical sympathectomy have also been equivocal. Oxygen is of help only at high altitudes. Meticulous local care, prevention of infection, and keeping the rewarmed area dry, open, and sterile provide optimal results. Recovery can be complete, and prolonged observation with conservative therapy is justified before any excision or amputation of tissue is considered. Analgesia and maintenance of good nutrition are necessary throughout the prolonged waiting period.

**Hypothermia**

Hypothermia may occur in winter sports when injury, equipment failure, or exhaustion decreases the level of exertion, particularly if sufficient attention is not paid to wind chill. Immersion in frozen bodies of water and wet wind chill rapidly produce hypothermia. As the core temperature of the body falls, insidious onset of extreme lethargy, fatigue, incoordination, and apathy occurs, followed by mental confusion, clumsiness, irritability, hallucinations, and finally, bradycardia. A number of medical conditions, such as cardiac disease, diabetes mellitus, hypoglycemia, sepsis, β-blocking agent overdose, and substance abuse, may need to be considered in a differential diagnosis. The decrease in rectal temperature to <34°C (93°F) is the most helpful diagnostic feature. Hypothermia associated with drowning is discussed in Chapter 74.

Prevention is a high priority. Of extreme importance for those who participate in winter sports is wearing layers of warm clothing, gloves, socks within insulated boots that do not impede circulation, and a warm head covering, as well as application of adequate waterproofing and protection against the wind. Thirty percent of heat loss for infants occurs from the head. Ample food and fluid must be provided during exercise. Those who participate in sports should be alert to the presence of cold or numbing of body parts, particularly the nose, ears, and

extremities, and they should review methods to produce local warming and know to seek shelter if they detect symptoms of local cold injury. Application of petrolatum (Vaseline) to the nose and ears gives certain protection against frostbite.

Treatment at the scene aims at prevention of further heat loss and early transport to adequate shelter (Table 76-2). Dry clothing should be provided as soon as practical, and transport should be undertaken if the victim has a pulse. If no pulse is detected at the initial review, cardiopulmonary resuscitation is indicated (see Chapter 67; Fig. 76-1). During transfer, jarring and sudden motion should be avoided because these occurrences may cause ventricular arrhythmia. It is often difficult to attain a normal sinus rhythm during hypothermia.

If the patient is conscious, mild muscle activity should be encouraged, and a warm drink offered. If the patient is unconscious, external warming should be undertaken initially with use of blankets and a sleeping bag; wrapping the patient in blankets or sleeping bag with a warm companion may increase the efficiency of warming. On arrival at a treatment center while a warming bath of 45–48°C (113–118°F) water is prepared, the patient should be warmed through inhalation of warm, moist air or oxygen or with heating pads or thermal blankets. Monitoring of serum chemistry values and an electrocardiogram are

ECG, electrocardiogram; CPR, cardiopulmonary resuscitation; HPMK, Hypothermia Prevention Management Kit; IV, intravenous; IO, intraosseous; ETCO2, end-tidal carbon dioxide; VT, ventricular tachycardia; VF, ventricular fibrillation; AED, automatic external defibrillator; US, ultrasound; ICU, intensive care unit; ECC, extracorporeal circulation. (From Zafren K, Giesbrecht GG, Danzl DF, et al: Wilderness Medical Society Practice Guidelines for the Out-of-Hospital Evaluation and Treatment of Accidental Hypothermia: 2014 Update, Wilderness Environ Med 25:S66–S85, 2014. Fig 2.)
necessary until the core temperature rises to >35°C (95°F) and can be stabilized. Control of fluid balance, pH, blood pressure, and oxygen concentration is necessary in the early phases of the warming period and resuscitation. In severe hypothermia, there may be a combined respiratory and metabolic acidosis. Hypothermia may falsely elevate pH; nonetheless, most authorities recommend warming the arterial blood gas specimen to 37°C (98.6°F) before analysis and regarding the result as one from a normothermic patient. In patients with marked abnormalities, warming measures, such as gastric or colonic irrigation with warm saline or peritoneal dialysis, may be considered, but the effectiveness of these measures in treating hypothermia is unknown. In accidental deep hypothermia (core temperature 28°C [82.4°F]) with circulatory arrest, rewarming with cardiopulmonary bypass may be lifesaving for previously healthy young individuals. If rewarming is not successful despite appropriate measures, one should suspect infection, drug overdose, endocrine disorders, or a futile resuscitation.

Chilblain (Pernio)
Chilblain (pernio) is a form of cold injury in which erythematous, vesicular, or ulcerative lesions occur. The lesions are presumed to be of vascular or vasoconstrictive origin. They are often itchy, may be painful, and result in swelling and scabbing. The lesions are most often found on the ears, the tips of the fingers and toes, and exposed areas of the legs. The lesions last for 1-2 wk but may persist for longer. Treatment consists of prophylaxis: avoiding prolonged chilling and protecting potentially susceptible areas with a cap, gloves, and stockings. Prazosin and phenoxybenzamine may be helpful in improving circulation if this is a recurrent problem. For significant itching, local corticosteroid preparations may be helpful.

COLD-INDUCED FAT NECROSIS (PANNICULITIS)
A common, usually benign injury, cold-induced fat necrosis occurs upon exposure to cold air, snow, or ice and manifests in exposed (or, less often, covered) surfaces as red (or, less often, purple to blue) macular, papular, or nodular lesions. Treatment is with nonsteroidal antiinflammatory agents. The lesions may last 10 days to 3 wk (see Chapter 660) but may persist for longer. There is a possibility of severe coagulopathy associated with poor outcome in some of the severe cold injuries, thus meriting anticoagulation therapy.

Genetic testing involves analyzing genetic material to obtain information related to a person's health status using chromosomal (cytogenetic) analysis (see Chapter 81) or DNA-based testing.

**DIAGNOSTIC TESTING**

Diagnostic genetic testing helps explain a set of signs and/or symptoms of a disease. The list of disorders for which specific genetic tests is available is extensive. The website http://www.ncbi.nlm.nih.gov/gtr/ provides a database of available tests that is provider driven and so claims are not validated by the site's host, the National Institutes of Health.

Single-gene disorders can be tested by at least 3 different approaches: linkage analysis, array comparative genomic hybridization (aCGH), and direct mutation (DNA sequence-based) analysis, usually by DNA sequencing (Table 77-1). Linkage analysis is used if the responsible gene is mapped but not yet identified, or if it is impractical to find specific mutations, usually because of the large size and larger number of different mutations in some genes. aCGH can be used to detect large multigene deletions or duplications (copy number variations). In addition, with increasing resolution, single gene or smaller intragenic deletions or duplications can be detected by aCGH. *Direct DNA mutation analysis* is preferred and is possible with the availability of the complete human genome sequence. An emerging feature is the increasing recognition of oligogenic disease where more than 1 disease gene contributes to a complex phenotype. The ability to sequence hundreds to thousands of genes at once has provided insight into this added layer of complexity in disease pathogenesis.

**Linkage testing** involves tracking a genetic trait through a family using closely linked polymorphic markers as a surrogate for the trait (Fig. 77-1). It requires testing an extended family and is vulnerable to several pitfalls, such as genetic recombination, genetic heterogeneity, and incorrect diagnosis in the proband. Genetic recombination occurs between any pair of loci, the frequency being proportional to the distance between them. This problem can be ameliorated by using very closely linked markers and, if possible, using markers that flank the specific gene. Genetic heterogeneity can be problematic for a linkage-based test if there are multiple distinct genomic loci that can cause the same phenotype, resulting in the risk that the locus tested for is not the one responsible for disease in the family. Incorrect diagnosis in the proband also leads to tracking the wrong gene. Linkage testing remains useful for several genetic conditions, though it is increasingly being superseded by the availability of direct DNA sequencing. It is critically important that genetic counseling be provided to the family to explain the complexities of interpretation of test results.

aCGH (see Chapter 81) can detect copy number variation in a patient's DNA by comparing it to a standard control DNA. In so doing, it provides a level of genetic resolution between what is available with DNA sequencing and what is available with chromosome analysis. Whereas earlier technologies could only identify large deletions or duplications that might encompass multiple genes, aCGH can resolve deletions or duplications of several kilobases within 1 gene. In theory, this approach can detect deletion and duplication mutations that would be missed by either chromosome analysis or direct mutation testing by DNA sequencing. However, because the specific resolution and coverage of different aCGH platforms can vary tremendously for different gene regions, the sensitivity for detecting deletions and duplications can vary for different diseases and laboratories.

**Direct DNA-based mutation testing** avoids the pitfalls of linkage testing by detecting the specific gene mutation (i.e., sequence change). The specific approach used is customized to the biology of the gene being tested. In some disorders, 1 or a few distinct mutations occur in all affected individuals. This is the case in sickle cell anemia, in which the same single base substitution occurs in everyone with the disorder. In other conditions, there may be many possible mutations that account for the disorder in different individuals. Cystic fibrosis is an example: more than 1,000 distinct mutations have been found in the CFTR gene. Mutation analysis is challenging because no single technique can detect all possible mutations. However, with the completion of the human genome sequence and high-throughput DNA sequencing technology, the approach of choice is to directly sequence DNA that is generated by polymerase chain reaction (PCR) amplification of DNA isolated from peripheral blood white blood cells. The limitation of this approach is that only DNA that is amplified is sequenced, and usually this is restricted to the coding or exonic regions of a gene. Because mutations sometimes occur in the noncoding intronic regions, failure to detect a mutation does not exclude the diagnosis. In addition, genes in a deleted region will not be deleted. Although DNA sequencing can be highly specific, it is not completely sensitive because of practical limitations of what is commercially available. This is, however, rapidly changing because of technologic advances.

The most useful development in clinical DNA diagnosis is application of *next-generation sequencing* technology to testing panels of genes that target disease symptoms (e.g., low bone mass, ataxia) or the whole exome (whole exome sequencing [WES]). Here, advances in sequencing methodology have allowed for massively parallel sequencing of hundreds of genes of all of the gene coding sequences (approximately 20,000 genes) from single sample. The challenge is not so much the generation of DNA sequence, but the interpretation of enormous genetic variation within a single sample. Direct sequencing of tens to hundreds of genes in next generation sequencing panels offer a potentially higher sensitivity as the “depth” of read is higher without complicating high discovery rate of variants of unknown sequences (VUS). WES also offers the potential for identifying new disease-gene associations as well as phenotypes caused by more than one disease gene (i.e., oligogenic phenotypes). An important ethical consideration is the reporting of incidental findings, whether medically or nonmedically actionable in a patient; WES may identify mutations that cause aminoglycoside sensitive hearing loss. This would be medically actionable. At the same time, the discovery of apolipoprotein E variants in a child that increase Alzheimer disease risk susceptibility may not. Hence, counseling for patients undergoing WES is important so that only wanted results are reported back to the patient. Guidelines are currently evolving for reporting of incidental findings for WES by the American College of Medical Genetics (www.acmg.net). Practice varies among institutions and recommendations vary among international genetic organizations about the approach for revealing incidental findings to patients. Many leave the choice up to the patient/family about revealing incidental findings from WES/whole genome sequencing. Most require revealing to the patient/family significant diseases

Figure 77-1 Use of linkage analysis in prenatal diagnosis of an autosomal recessive disorder. Both parents are carriers, and they have 1 affected son. The numbers below the symbols indicate alleles at 3 polymorphic loci: A, B, and C. Locus B resides within the disease gene. The affected son inherited the 1-2-2 chromosome from his father and the 2-1-2 chromosome from his mother. The fetus has inherited the same chromosome from the father, but the 3-2-4 chromosome from the mother and therefore is most likely to be a carrier.

Pathogenicity. These include finding the variant only in affected individuals, inferring that the variant alters the function of the gene product, determining whether the amino acid altered by the mutation is conserved in evolution, and determining whether the mutation segregates with disease in the family. In some cases, it is possible to be sure whether the variant is pathogenic or incidental. In spite of all of these approaches, it might still be impossible to definitively assign causality with 100% confidence.

False-negative results reflect an inability to detect a mutation in an affected patient. This occurs principally in disorders where genetic heterogeneity—allellic (different mutations occur in one causative gene) heterogeneity or locus (more than one gene can cause a disease) heterogeneity—is the rule. It is difficult to detect all possible mutations within a gene, because mutations can be varied in location within the gene and in the type of mutation. Direct sequencing may miss gene deletions or rearrangements, and mutations may be found within non-coding sequences such as introns or the promoter; a negative DNA test does not necessarily exclude a diagnosis.

Clinical validity is the degree to which the test correctly predicts presence or absence of disease. False-positive and false-negative test results can occur. False-positive results are more likely for predictive tests than for diagnostic tests. An important contributing factor is nonpenetrance: An individual with an at-risk genotype might not clinically express the condition. Another factor is the finding of a genetic variant of unknown significance. Detection of a base sequence variation in an affected patient does not prove that it is the cause of the patient’s disorder. In exomic sequencing, there may be more than 30,000 VUS; in whole genome sequencing there may be more than 3,000,000 VUS. Various lines of evidence are used to establish pathogenicity. These include finding the variant only in affected individuals, inferring that the variant alters the function of the gene product, determining whether the amino acid altered by the mutation is conserved in evolution, and determining whether the mutation segregates with disease in the family. In some cases, it is possible to be sure whether the variant is pathogenic or incidental. In spite of all of these approaches, it might still be impossible to definitively assign causality with 100% confidence.

False-negative results reflect an inability to detect a mutation in an affected patient. This occurs principally in disorders where genetic heterogeneity—allellic (different mutations occur in one causative gene) heterogeneity or locus (more than one gene can cause a disease) heterogeneity—is the rule. It is difficult to detect all possible mutations within a gene, because mutations can be varied in location within the gene and in the type of mutation. Direct sequencing may miss gene deletions or rearrangements, and mutations may be found within non-coding sequences such as introns or the promoter; a negative DNA test does not necessarily exclude a diagnosis.

Clinical validity is the degree to which the results of a test guide clinical management. For genetic testing, clinical utility includes establishing a diagnosis that obviates the need for additional workup or guiding surveillance or treatment. Test results may also be used as a basis for genetic counseling. For some disorders, genetic testing is possible but the test results do not add to the clinical assessment. If the diagnosis and genetic implications are already clear, it might not be necessary to pursue genetic testing.

PREDICTIVE TESTING

Predictive genetic testing involves performing a test in a person who is at risk for developing a genetic disorder (presymptomatic), usually on the basis of family history, yet who does not manifest signs or
symptoms. This is usually done for disorders that display age-dependent penetrance; the likelihood of manifesting signs and symptoms increases with age, as in cancer or Huntington disease.

A major caution with predictive testing is that the presence of a gene mutation does not necessarily mean that the disease will develop. Many of the disorders with age-dependent penetrance display incomplete penetrance. A person who inherits a mutation might never develop signs of the disorder. There is concern that a positive DNA test could result in stigmatization of the person and might not provide information that will guide medical management. Stigmatization might include psychological stress, but it could also include discrimination, including denial of health, life, or disability insurance, or employment (see Chapter 78).

It is generally agreed that predictive genetic tests should be performed for children if the results of the test will benefit the medical management of the child. Otherwise, the test should be deferred until the child has an understanding of the risks and benefits of testing and can provide informed consent. Individual states offer varying degrees of protection from discrimination on the basis of genetic testing. A major milestone in the prevention of genetic discrimination was the passage of the Genetic Information Nondiscrimination Act (GINA) in 2008, which is a federal law that prohibits discrimination in health coverage or employment based on genetic information; it does not protect against refusal of life insurance.

**PREDISPOSITIONAL TESTING**

It is expected that genetic tests will become available that will predict risk of disease. Common disorders are multifactorial in etiology; there may be many different genes that contribute to risk of any specific condition (see Chapter 82). Most of the genetic variants that have been found to correlate with risk of a common disease add small increments of relative risk, probably in most cases too little to guide management. It is possible that further discovery of genes that contribute to common disorders will reveal examples of variants that convey more significant levels of risk. It is also possible that testing several genes together will provide more information about risk than any individual gene variant would confer. The rationale for predispositional testing is that the results would lead to strategies aimed at risk reduction as part of a personalized approach to healthcare maintenance. This might include avoidance of environmental exposures that would increase risk of disease (cigarette smoking and α1-antitrypsin deficiency), medical surveillance (familial breast cancer and mammography), or, in some cases, pharmacologic (statins and hypercholesteremia) treatment. The value of predispositional testing will need to be critically appraised through outcomes studies as these tests are developed.

**PHARMACOGENETIC TESTING**

Polymorphisms in drug metabolism genes can result in distinctive patterns of drug absorption, metabolism, excretion, or effectiveness (see Chapters 59 and 82). Knowledge of individual genotypes will guide pharmacologic therapy, allowing customization of choice of drug and dosage to avoid toxicity and provide a therapeutic response. An example of this is testing for polymorphisms within the methylenetetrahydrofolate reductase (MTHFR) gene for susceptibility of potentially increased toxicity to methotrexate antimetabolite therapy for treatment of acute lymphoblastic leukemia.

### 77.1 Genetic Counseling

**Brendan Lee**

Genetic counseling is a communication process in which the genetic contribution to health is explained, along with specific risks of transmission of a trait and options to manage the condition and its inheritance (Table 77-3). The counselor is expected to present information in a neutral, nondirective manner and to provide support to the individual and family to cope with decisions that are made.

</table>
as much information and as many options as are available. The fourth situation is counselling prior to genome sequencing where the family is given options of what they want reported back to them (actionable, nonactionable incidental findings vs. a specific diagnosis).

GENETIC COUNSELING
Providing accurate information to families requires:
- Taking a careful family history and constructing a pedigree that lists the patient’s relatives (including abortions, stillbirths, deceased persons) with their sex, age, and state of health, up to and including 3rd-degree relatives.
- Gathering information from hospital records about the affected individual and, in some cases, about other family members.
- Documenting prenatal, pregnancy, and delivery histories.
- Reviewing the latest available medical, laboratory, and genetic information concerning the disorder.
- Performing a careful physical examination of the affected individual (photographs, measurements) and of apparently unaffected individuals in the family.
- Establishing or confirming the diagnosis by the diagnostic tests available.
- Giving the family information about support groups.
- Providing new information to the family as it becomes available (a mechanism for updating needs to be established).

Counseling sessions must include the specific condition, knowledge of the diagnosis of the particular condition, the natural history of the condition, the genetic aspects of the condition and the risk of recurrence, prenatal diagnosis and prevention, therapies and referral, support groups, and nondirective counseling.

Specific Condition or Conditions
If a specific diagnosis is made and confirmed, that should be discussed with the family and information should be provided in writing. However, often the disorder fits into a spectrum (e.g., one of many types of arthrogryposis) or the diagnosis is clinical rather than laboratory based. In those situations, the family needs to understand the limits of present knowledge and that additional research will probably lead to better information in the future.

Knowledge of the Diagnosis of the Particular Condition
Although it is not always possible to make an exact diagnosis, having a diagnosis as accurate as possible is important. Estimates of recurrence risk for various family members depend on an accurate diagnosis. When a specific diagnosis cannot be made (as in many cases of multiple congenital anomalies), the various possibilities in the differential diagnosis should be discussed with the family and empirical information should be provided. If specific diagnostic tests are available, they should be discussed. Often, empirical recurrence risks can be given even without a specific laboratory-based diagnosis. At the same time, even negative laboratory testing can further modify this risk.

Natural History of the Condition
It is very important to discuss the natural history of the specific genetic disorder in the family. Affected persons and their families have questions regarding the prognosis and potential therapy that can be answered only with knowledge of the natural history. If there are other possible diagnoses, their natural history may also be discussed. If the disorder is associated with a spectrum of clinical outcomes or complications, the worst and best scenarios, as well as treatment and referral to the appropriate specialist, should be addressed.

Genetic Aspects of the Condition and Recurrence Risk
The genetic aspects and risk of recurrence are important because all family members need to be aware of their reproductive choices. The genetics of the disorder can be explained with visual aids (e.g., diagrams of chromosomes). It is important to provide accurate occurrence and recurrence risks for various members of the family, including unaffected individuals. If a definite diagnosis cannot be made, it is necessary to use empirical recurrence risks. Counseling should give patients the necessary information to understand the various options and let the patients make their own informed decisions regarding pregnancy, adoption, artificial insemination, prenatal diagnosis, screening, carrier detection, and termination of pregnancy. It may be necessary to have more than 1 counseling session.

Prenatal Diagnosis and Prevention
Many different methods of prenatal diagnosis are available, depending on the specific genetic disorder (see Chapter 96). The use of ultrasonography allows prenatal diagnosis of anatomic abnormalities such as congenital heart defects. Amniocentesis and chorionic villus sampling are used to obtain fetal tissue for analysis of chromosomal abnormalities, biochemical disorders, and DNA studies. Maternal blood or serum sampling is used for some types of screening. Fetal cells can be retrieved from the umbilical cord or from maternal blood (free fetal DNA) for testing, although mothers might harbor cells from all previous pregnancies.

Therapies and Referral
A number of genetic disorders require the care of a specialist. Girls with Turner syndrome usually need to be evaluated by an endocrinologist. Prevention of known complications is a priority. The psychological adjustment of the family might require specific intervention. When to discuss the diagnosis of a chronic disease with the patient is always a difficult decision. The decision to do so should always involve the parents and an assessment of the maturity and capacity of the child or adolescent.

Alternative medicines or nontraditional therapies are often brought to attention by parents after exhaustive Internet searches. Such treatments should not necessarily be dismissed out of hand because the physician and counselor should serve as an important resource for helping parents navigate the maze of nonstandard treatments. Instead, the relative merits of treatments should be framed in the context of cost and benefit, scientific rationale, evidence from controlled and/or observational studies, the placebo effect, safety of the treatment, and the gaps in our own scientific knowledge base.

Support Groups
A large number of community lay support groups have been formed to provide information and to fund research on specific genetic and nongenetic conditions. An important part of genetic counseling is to give information about these groups to patients and to suggest a contact person for the families. Many groups have established websites with very helpful information; it is important to stress to families that their individual disease course will be unique.

Follow-up
Families should be encouraged to continue to ask questions and keep up with new information about the specific disorder. New developments often influence the diagnosis and therapy of specific genetic disorders. Lay support groups are a good source of new information.

Nondirective Counseling
Genetic counseling is usually nondirective; choices about reproduction are left to the family to decide what is right for them. The role of the counselor (physician, genetic counselor, nurse, medical geneticist) is to provide information in understandable terms and outline the range of options available.

77.2 Management and Treatment of Genetic Disorders

Brendan Lee

Genetic conditions are often chronic disorders; few are amenable to curative therapies. Nevertheless, many management options are
available. All patients and families should be provided information about the disorder, genetic counseling, anticipatory guidance, and appropriate medical surveillance. Surgical management is available for many conditions that are associated with congenital anomalies or predisposition to tumors.

Resources for patients include the National Organization of Rare Disorders (www.rarediseases.org), the Genetic Alliance (www.geneticalliance.org), the National Library of Medicine (www.nlm.nih.gov/medlineplus/geneticdisorders.html), and a large number of disease-specific websites. A current listing of federally and privately funded clinical trials, including many for genetic diseases, is available at www.ClinicalTrials.gov.

Specific medical therapies for genetic disorders can be classified into physiologic and replacement therapies. Much effort is currently focused in developing gene and cell therapies.

PHYSIOLOGIC THERAPIES

Physiologic therapies attempt to ameliorate the phenotype of a genetic disorder by modifying the physiology of the affected individual. The underlying defect itself is not altered by treatment. Physiologic therapies are used in the treatment of inborn errors of metabolism (see Chapter 84). These include dietary manipulation, such as avoiding phenylalanine by persons with phenylketonuria; coenzyme supplementation for some patients with methylmalonic acidemia and mitochondrial diseases; stimulation of alternative pathways to excrete ammonia for those with urea cycle disorders; bisphosphonate treatment for those with osteogenesis imperfecta to reduce bone fractures; and avoiding cigarette smoking by persons with α1-antitrypsin deficiency. Physiologic treatments can be highly effective, but they usually need to be maintained for a lifetime because they do not affect the underlying genetic disorder. Many of these treatments are most effective when begun early in life before irreversible damage has occurred. This is the rationale for comprehensive newborn screening for inborn errors of metabolism.

Many physiologic therapies use small-molecule pharmaceuticals (e.g., to remove ammonia in those with urea cycle disorders). Pharmacologic treatments directly target a defective cellular pathway that is altered by an abnormal or a missing gene product. However, there are relatively few such therapies. One example is the development of imatinib, a small molecule tyrosine kinase inhibitor developed specifically to target the biologic pathway altered in chronic myelogenous leukemia (CML). CML is usually associated with a chromosome 9,22 translocation (the Philadelphia chromosome) that creates a fusion of the BCR protein and the Abl oncogene. Imatinib is a small molecule that blocks the adenosine triphosphate binding in the fusion protein; it is highly effective in treatment of CML and several other malignancies. Other examples include large-molecule biologics such as “humanized” monoclonal antibodies.

REPLACEMENT THERAPIES

Replacement therapies include replacement of a missing metabolite, an enzyme, an organ, or even a specific gene.

Enzyme Replacement

Enzyme replacement therapy is a component of the treatment of cystic fibrosis to manage intestinal malabsorption. Pancreatic enzymes are easily administered orally, because they must be delivered to the gastrointestinal tract.

Enzyme replacement strategies are effective for some lysosomal storage disorders. Enzymes are targeted for the lysosome by modification with mannose-6-phosphate, which binds to a specific receptor. This receptor is also present on the cell surface, so lysosomal enzymes with exposed mannose-6-phosphate residues can be infused into the blood and are taken into cells and transported to lysosomes. Enzyme replacement therapies are available for Gaucher disease and Fabry disease, some mucopolysaccharidoses (I, II, VI), Niemann-Pick disease type C, and Pompe disease.

One complication of enzyme replacement therapy is antibody response to the enzyme. The magnitude of this response is not always predictable and varies depending on the enzyme preparation and the disease. In most cases, the patient’s antibody response does not affect the treatment’s efficacy (e.g., in Gaucher disease), but in other situations it may be a significant hurdle (e.g., in Pompe disease).

Transplantation

Cell and organ transplantation are potentially effective approaches to replacement of a defective gene. Aside from transplantation to replace damaged tissues, transplantation of stem cells, liver, or bone marrow is also used for several diseases, mainly inborn errors of metabolism, and hematologic or immunologic disorders. A successful transplant is essentially curative, though there may be significant risks and side effects (see Chapters 135-139). Cell and tissue transplantation are effective in many clinical scenarios, but there is always short-term morbidity, often associated with either surgical (liver) or preparative (bone marrow) regimens, and long-term morbidity related to chronic immunosuppression and graft failure. Bone marrow transplantation is the best example of stem cell therapy, but much effort is focused on identifying, characterizing, expanding, and using other tissue stem cells for regenerative therapies.

Alternatively, research has focused on replacing a defective gene (gene therapy). In theory, if we can target the specific tissue that has a deficiency in the gene or gene product, this can offer a less invasive means of achieving a cure of a genetic disorder. Ultimately, gene therapy depends on the unique interaction of the disease pathophysiology, which is specific to the patient, and the gene delivery vehicle.

Gene-transfer vehicles include viral and nonviral approaches. Most human clinical trials have used viral vectors because of their efficiency of tissue transduction. In some diseases, such as X-linked and adenosine deaminase-deficient severe combined immunodeficiency, clinical gene therapy is a viable and effective option (see Chapter 126.1). Preliminary results suggest that gene therapy (intraocular delivery) may be effective for Leber congenital amaurosis.

Bibliography

Manolio TA: Cohort studies and genetics of complex disease, Nat Genet 41:5–6, 2009.

Since the completion of the Human Genome Project, we have seen an unprecedented expansion in our understanding of how human health is impacted by variations in genomic sequence and epigenetic, non-sequence-based, changes that affect gene expression. This period has also seen the development and implementation of new clinical tests that have made it easier for physicians to detect such changes. In addition, this period has seen a dramatic increase in the availability of information about the genetic aspects of pediatric diseases, particularly on the Internet (Table 78-1).

THE BURDEN OF GENETIC DISORDERS IN CHILDHOOD

Medical problems associated with genetic disorders can appear at any age with the most obvious and serious problems typically manifesting in childhood. It has been estimated that 53/1,000 children and young adults can be expected to have diseases with an important genetic component. If congenital anomalies are included, the rate increases to 79/1,000. In 1978, it was estimated that just over half of admissions to
pediatric hospitals were for a genetically determined condition. By 1996, owing to changes in healthcare delivery and a greater understanding of the genetic basis of many disorders, that percentage rose to 71% in 1 large pediatric hospital in the United States, and 96% of chronic disorders leading to admission had an obvious genetic component or were influenced by genetic susceptibility. Major categories of genetic disorders include single-gene, genomic, chromosomal, and multifactorial conditions.

Individually, single-gene disorders are rare, but collectively they represent an important contribution to childhood disease. The hallmark of a single-gene disorder is that the phenotype is overwhelmingly determined by changes that affect an individual gene. The phenotypes associated with single-gene disorders can vary from one patient to another based on the severity of the change affecting the gene and additional modifications caused by genetic, environmental, and/or stochastic factors. This feature of genetic disease is termed variable expressivity. Common single-gene disorders include sickle cell anemia and cystic fibrosis.

Single-gene disorders tend to occur when changes in a gene have a profound effect on the quantity of the gene product produced—even too much or too little—or the function of the gene product—either a loss of function or a harmful gain of function. Single-gene disorders can be caused by de novo changes that are not found in the unaffected parents of the affected individual or they may be caused by inherited changes. When a single-gene disorder is known to be caused by changes in only 1 gene or a small number of individual genes, searching for deleterious changes is most often performed by directly sequencing that gene and, in some cases, looking for small deletions and/or duplications. When multiple genes can potentially cause a particular disorder, it is sometimes more efficient and cost effective to screen large numbers of disease causing genes using a disease-specific panel that takes advantage of next generation sequencing technology than to screen genes individually. When such panels are not available, or when the diagnosis is in question, physicians may consider screening the protein coding regions of all genes by whole exome sequencing on a clinical basis. Indeed in many circumstances, whole exome sequencing is less expensive than sequencing multiple individual genes. In the future, whole genome sequencing—in which an individual’s entire genome is sequenced—may become a valid clinical option as the cost of such tests fall and our ability to interpret the clinical consequences of thousands of changes that are identified in such tests improves.

The risk of having a child with a particular single gene disorder can vary from one population to another. In some cases this is the result of a founder effect, in which a specific change affecting a disease-causing gene becomes relatively common in a population derived from a small number of founders. This high frequency is maintained when there is relatively little interbreeding with persons outside of that population because of social, religious, or physical barriers. This is the case for Tay-Sachs disease in Ashkenazi Jews and French Canadians. Other changes may be subject to positive selection when found in the heterozygous carrier state. In this case, carriers of a genetic change (heterozygotes) have a survival advantage over noncarriers. This can occur even when individuals who inherit 2 copies of the change (homozygotes) have severe medical problems. This type of positive selection is evident among individuals in sub-Saharan Africa who carry a hemoglobin mutation that confers relative resistance to malaria but causes sickle cell anemia in homozygotes.

Genomic disorders are a group of diseases caused by alterations in the genome, including deletions (copy number loss), duplications (copy number gain), inversions (altered orientation of a genomic region) and chromosomal rearrangements (altered location of a genomic region). Contiguous gene disorders are caused by changes that affect two or more genes that contribute to the clinical phenotype and are located near each other on a chromosome. DiGeorge syndrome, which is caused by deletions of genes located on chromosome 22q11, is a common example. Some genomic disorders are associated with distinctive phenotypes whose pattern can be recognized clinically. Other genomic disorders do not have a distinctive pattern of anomalies, but can cause developmental delay, cognitive impairment, structural birth defects, abnormal growth patterns and changes in physical appearance. Fluorescent in situ hybridization (FISH) can provide information about the copy number and location of a specific genomic region. Array-based copy number detection assays can be used to screen for chromosomal deletions (large and small) and duplication across the genome but do not provide information about the orientation or location of genomic regions. A chromosome analyses (karyotyping) can detect relatively large chromosomal deletions and duplications and can also be useful in identifying inversions and chromosomal rearrangements even when they are copy-number neutral.
changes that do not result in a deletion or duplication of genomic material. Deletions, duplications, and chromosomal rearrangements that affect whole chromosomes, or large portions of a chromosome, are commonly referred to as chromosomal disorders. One of the most common chromosomal disorders is Down syndrome, which is most commonly associated with the presence of an extra copy, or trisomy, of an entire chromosome 21. When all or a part of a chromosome is missing, the disorder is referred to as monosomy. Translocations are a type of chromosomal rearrangement in which a genomic region from 1 chromosome is transferred to a different location on the same chromosome or on a nonhomologous chromosome. Translocations can be balanced, meaning that no genetic material has been lost or gained, or they can be unbalanced, in which case some genetic material has been deleted or duplicated. Chromosomal disorders can often be identified on a chromosome analysis (karyotype) or by FISH. Evidence of a chromosomal disorder may also be revealed by an array-based copy number detection assays if genetic material has been gained or lost.

In some cases, only a portion of cells that make up a person's body are affected by the single gene defect, the genomic disorder or the chromosomal defect. This is referred to as mosaicism and indicates that the individual's body is made up of 2 or more distinct cell populations. Polygenic disorders are caused by the cumulative effects of changes or variations in more than 1 gene. Multifactorial disorders are caused by the cumulative effects of changes or variations in multiple genes and/or the combined effects of both genetic and environmental factors. Spina bifida and isolated cleft lip or palate are common birth defects that display multifactorial inheritance patterns. Multifactorial inheritance is seen in many common pediatric disorders, such as asthma and diabetes mellitus. These traits can cluster in families but do not have a mendelian pattern of inheritance (see Chapter 80). In most cases, the genetic changes or variations that are contributing to a particular case are unknown and genetic counseling is based on empirical data.

**THE CHANGING PARADIGM OF GENETICS IN MEDICINE**

Genetic testing is increasingly available for a wide variety of both rare and relatively common genetic disorders. Genetic testing is commonly used in pediatric medicine to resolve uncertainty regarding the underlying etiology of a child's medical problems and provides a basis for improved genetic counseling and possibly specific therapy. Even in cases where a specific treatment is not available, identifying a genetic cause can aid physicians in providing individuals and family with accurate prognostic and recurrence risk information and usually helps to relieve unfounded feelings of guilt and/or stem the tide of misdirected blame.

Genetic tests will ultimately come to underlie a high proportion of medical decisions and will be seamlessly incorporated into routine medical care. Although most genetic testing is presently aimed at identifying or confirming a diagnosis, in the future, genetic testing may find wider application as a means of determining if an individual is predisposed to develop a particular disease. Another area in which genetic testing could make a significant impact is on individualized drug treatment. It has long been known that genetic variation in the enzymes involved in drug metabolism underlies differences in the therapeutic effect and toxicity of some drugs. As the genetic changes that underlie these variations are identified, new genetic tests may be developed that will allow physicians to tailor treatments based on individual variations in drug metabolism, responsiveness, and susceptibility to toxicity (see Chapter 59). It is likely that the expansion of such testing will depend, at least in part, on the extent to which such testing can be linked to strategies to prevent disease or improve outcome (see Chapter 77). If such links can be made, it could usher in a new era of personalized medical treatment.

Long-standing and highly successful carrier screening programs have existed for disorders such as Tay-Sachs disease and many other rare single-gene disorders that are prevalent in specific populations. Couples are commonly offered screening for a variety of conditions, in part based on ancestry (Tay-Sachs disease, hemoglobinopathies, cystic fibrosis). Couples found to be at increased risk for such disorders can be offered preconception or prenatal testing aimed at detecting specific disease causing mutations.

Prenatal screening is routinely offered for chromosomal disorders such as trisomy 13, trisomy 18, and Down syndrome. An increasing number of pregnancies affected by these and other genetic disorders are being recognized by noninvasive screening tests of maternal serum in the first and second trimesters and by fetal ultrasound. When genetic disorders are suspected, chorionic villus sampling at 10-12 wk of gestation or by amniocentesis at 16-18 wk of gestation can provide material for genetic testing. Approaches to noninvasive prenatal diagnosis by sampling of cell-free fetal DNA or fetal cells in maternal blood are also becoming available. When a couple is at risk for a specific genetic defect, preimplantation genetic diagnosis can sometimes be used to select unaffected early embryos, which are then implanted as part of an in vitro fertilization procedure.

Although prenatally obtained genetic material can be used to identify single-gene disorders, genomic disorders, and chromosomal anomalies, the information obtained on any pregnancy depends on the tests that are ordered. It is important that physicians select the most appropriate prenatal tests and that couples understand both the limitations of these tests and that no amount of genetic testing can guarantee the birth of a healthy child.

Specific treatments are not available for the majority of genetic disorders. However, there are some important exceptions. Inborn errors of metabolism were the first genetic disorders to be recognized, and many are amenable to treatment by dietary manipulation (see Chapter 84). These conditions result from genetically determined deficiency of specific enzymes, leading to the buildup of toxic substrates and/or deficiency of critical end products.

Individual metabolic disorders tend to be very rare, but their combined impact on the pediatric population is significant. Tandem mass spectrometry has made it relatively inexpensive to screen for a large number of these disorders in the newborn period. Use of this technology not only dramatically increases the number of metabolic disorders identified within a population but also allows treatment to be initiated at a much earlier stage in development (see Chapters 77 and 84).

Another area where progress has been made regarding genetic therapies has been in the treatment of lysosomal storage disorders. These are a group of metabolic diseases caused by defects in lysosomal function. Lysosomes are cellular organelles that contain specific digestive enzymes. Some of these disorders that were lethal or associated with intractable chronic illness can now be treated using specially modified enzymes that are administered by intravenous infusion. These enzymes are then taken up by cells and incorporated into lysosomes. Conditions such as Gaucher disease and Fabry disease are routinely treated using enzyme replacement, and similar therapies are being developed for other lysosomal disorders.

Therapeutic advances are also being made in the treatment of nonmetabolic genetic disorders. Improvements in surgical techniques and intensive care medicine are extending the survival of children with life-threatening birth defects like congenital diaphragmatic hernia and severe cardiac defects. In many cases, the life expectancy of children with debilitating genetic disorders is also increasing. A good example is the increasing life expectancy of individuals with cystic fibrosis, largely owing to improvements in antibiotic therapy as well as the management of chronic pulmonary disease and malabsorption. A major consequence of these advances is that an increasing percentage of affected patients is surviving into adulthood, creating a need to transition care from pediatric to adult providers.

Gene-replacement therapies have long been anticipated. However, it has proved difficult to develop safe and effective approaches for inserting genes into diseased tissues in a way that allows physiologically meaningful levels of gene expression to be maintained over long periods. Stem cell-based therapies have also been touted as a potential treatment for a number of intractable disorders, but clear evidence that such therapies are effective has yet to materialize.
ETHICS ISSUES

Like all medical care, genetic testing, diagnosis, and treatment should be performed confidentially. Nothing is as personal as one's genetic information, and all efforts should be made to avoid any stigma for the patient. Many people fear that results of genetic testing will put them, or their child, at risk for genetic discrimination. Genetic discrimination occurs when people are treated unfairly because of a difference in their DNA that suggests that they have a genetic disorder or are at an increased risk of developing a certain disease. In the United States, the Genetic Information Nondiscrimination Act of 2008 protects individuals from genetic discrimination at the hands of health insurers and employers, but does not extend protection against discrimination from providers of life, disability, or long-term care insurance.

Like all medical decision-making, the decisions about genetic testing should be based on a careful evaluation of the potential benefits and risks. In the pediatric setting, these decisions may be more difficult because physicians and parents are often called on to make decisions for a child who cannot directly participate in discussions about the testing. Molecular diagnostic tests are often used to diagnose malformation syndromes, cognitive delay, or other disabilities wherein there is a clear benefit to the child. In other cases, such as genetic testing for susceptibility to adult-onset diseases, it is appropriate to wait until the child or adolescent is mature enough to weigh the pros and cons and make his or her own decisions about genetic testing.

Policies regarding genetic testing of children have been developed collaboratively by the American Academy of Pediatrics (AAP) and the American College of Medical Genetics and Genomics (ACMG; Pediatrics 131[3]:620-622, 2013). These recommendations are outlined here:

1. Decisions about whether to offer genetic testing and screening should be driven by the best interest of the child.

2. Genetic testing is best offered in the context of genetic counseling. Genetic counseling can be performed by clinical geneticists, genetic counselors, or any other health care provider with appropriate training and expertise. The AAP and ACMG support the expansion of educational opportunities in human genomics and genetics for medical students, residents, and practicing pediatric primary care providers.

Diagnostic Testing

3. In a child with symptoms of a genetic condition, the rationale for genetic testing is similar to that of other medical diagnostic evaluations. Parents or guardians should be informed about the risks and benefits of testing, and their permission should be obtained. Ideally, and when appropriate, the assent of the child should be obtained.

4. When performed for therapeutic purposes, pharmacogenetic testing of children is acceptable, with permission of parents or guardians and, when appropriate, the child's assent. If a pharmacogenetic test result carries implications beyond drug targeting or dose-responsiveness, the broader implications should be discussed before testing.

Newborn Screening

5. The AAP and ACMG support the mandatory offering of newborn screening for all children. After education and counseling about the substantial benefits of newborn screening, its remote risks, and the next steps in the event of a positive screening result, parents should have the option of refusing the procedure, and an informed refusal should be respected.

Carrier Testing

6. The AAP and ACMG do not support routine carrier testing in minors when such testing does not provide health benefits in childhood. The AAP and ACMG advise against school-based testing or screening programs, because the school environment is unlikely to be conducive to voluntary participation, thoughtful consent, privacy, confidentiality, or appropriate counseling about test results.

7. For pregnant adolescents or for adolescents considering reproduction, genetic testing and screening should be offered as clinically indicated, and the risks and benefits should be explained clearly.

Predictive Genetic Testing

8. Parents or guardians may authorize predictive genetic testing for asymptomatic children at risk of childhood-onset conditions. Ideally, the assent of the child should be obtained.

9. Predictive genetic testing for adult-onset conditions generally should be deferred unless an intervention initiated in childhood may reduce morbidity or mortality. An exception might be made for families for whom diagnostic uncertainty poses a significant psychosocial burden, particularly when an adolescent and his or her parents concur in their interest in predictive testing.

10. For ethical and legal reasons, healthcare providers should be cautious about providing predictive genetic testing to minors without the involvement of their parents or guardians, even if a minor is mature. Results of such tests may have significant medical, psychological, and social implications, not only for the minor but also for other family members.

Histocompatibility Testing

11. Tissue compatibility testing of minors of all ages is permissible to benefit immediate family members but should be conducted only after thorough exploration of the psychosocial, emotional, and physical implications of the minor serving as a potential stem cell donor. A donor advocate or similar mechanism should be in place from the outset to avert coercion and safeguard the interests of the child.

Adoption

12. The rationale for genetic testing of children in biological families should apply for adopted children and children awaiting placement for adoption. If a child has a known genetic risk, prospective adoptive parents must be made aware of this possibility. In rare cases, it may be in a child's best interest to undergo predictive genetic testing for a known risk before adoption to ensure the child's placement with a family capable of and willing to accept the child's potential medical and developmental challenges. In the absence of such indications, genetic testing should not be performed as a condition of adoption.

Disclosure

13. At the time of genetic testing, parents or guardians should be encouraged to inform their child of the test results at an appropriate age. Parents or guardians should be advised that, under most circumstances, a request by a mature adolescent for test results should be honored.

14. Results from genetic testing of a child may have implications for the parents and other family members. Healthcare providers have an obligation to inform parents and the child, when appropriate, about these potential implications. Healthcare providers should encourage patients and families to share this information and offer to help explain the results to the extended family or refer them for genetic counseling.

15. Misattributed paternity, use of donor gametes, adoption, or other questions about family relationships may be uncovered "incidentally" whenever genetic testing is performed, particularly when testing multiple family members. This risk should be discussed, and a plan about disclosure or nondisclosure should be in place before testing.

Direct-to-Consumer Testing

16. The AAP and ACMG strongly discourage the use of direct-to-consumer and home-kit genetic testing of children because of the lack of oversight on test content, accuracy, and interpretation.

Bibliography
The Human Genome Project, culminated in the sequencing of the human genome and greatly expanded our ability to study human genes and to explore the roles of genes in both rare and common disorders. Over time, it has also become apparent that the genome includes far more than a coded store of information to produce proteins.

The human genome has approximately 25,000 genes that encode the wide variety of proteins found in the human body. Reproductive or germ line cells contain 1 copy (N) of this genetic complement and are haploid, whereas somatic (non-germ line) cells contain 2 complete copies (2N) and are diploid. Genes are organized into long segments of DNA, which, during cell division, are compacted into intricate structures together with proteins to form chromosomes. Each somatic cell has 46 chromosomes: 22 pairs of autosomes, or nonsex chromosomes, and 1 pair of sex chromosomes (XY in a male, XX in a female). Germ cells (ova or sperm) contain 22 autosomes and 1 sex chromosome, for a total of 23. At fertilization, the full diploid chromosome complement of 46 is again realized in the embryo.

Most of the genetic material is contained in the cell’s nucleus. The mitochondria (the cell’s energy-producing organelles) contain their own unique genome. The mitochondrial chromosome consists of a double-stranded circular piece of DNA, which contains 16,568 base pairs (bp) of DNA and is present in multiple copies per cell. The proteins that occupy the mitochondria are produced either in the mitochondria, using information contained in the mitochondrial genome, or are produced outside of the mitochondria, using information contained in the nuclear genome and transported into the organelle. Sperm do not usually contribute mitochondria to the developing embryo, so all mitochondria are maternally derived and a child’s mitochondrial genetic makeup derives exclusively from the child’s biological mother.

**FUNDAMENTALS OF MOLECULAR GENETICS**

The central tenet of molecular genetics is that information encoded in DNA, predominantly located in the cell nucleus, is transcribed into messenger RNA (mRNA), which is then transported to the cytoplasm, where it is translated into protein. A gene is a unit that includes a regulatory region and a coding region that stores information corresponding to the sequence of amino acids in a specific protein.

DNA consists of a pair of chains of a sugar-phosphate backbone linked by pyrimidine and purine bases to form a double helix (Fig. 79-1). The sugar in DNA is deoxyribose. The pyrimidines are cytosine (C) and thymine (T); the purines are guanine (G) and adenine (A). The bases are linked by hydrogen bonds such that A always pairs with T and G with C. Each strand of the double helix has polarity, with a free phosphate at one end (5′) and an unbounded hydroxyl on the sugar at the other end (3′). The 2 strands are oriented in opposite polarity in the double helix.

The replication of DNA follows the pairing of bases in the parent DNA strand. The original 2 strands unwind by breaking the hydrogen bonds between base pairs. Free nucleotides, consisting of a base attached to a sugar-phosphate, form new hydrogen bonds with their complementary bases on the parent strand; new phosphodiester bonds are created by the enzyme DNA polymerase. Replication of chromosomes begins simultaneously at multiple sites, forming replication bubbles that expand bidirectionally until the entire DNA molecule (chromosome) is replicated. Errors in DNA replication, or mutations induced by environmental mutagens such as irradiation or chemicals, are detected and potentially corrected by DNA repair systems.

A prototypical gene consists of a regulatory region, segments called exons that encode the amino acid sequence of a protein, and intervening segments called introns (Fig. 79-2). Transcription starts at the promoter region and continues through the entire length of the gene to form mRNA. The introns are removed and the exons spliced together to form a mature message, which is exported to the cytoplasm. There the mRNA is bound to ribosomes and translated into protein.

Transcription is initiated by attachment of RNA polymerase to the promoter site upstream of the beginning of the coding sequence. Specific proteins bind to the region to either repress or activate transcription by opening up the chromatin, which is a complex of DNA and histone proteins. It is the action of these regulatory proteins (transcription factors) that determines, in large part, when a gene is turned on or off. Some genes are also turned on and off by methylation of cytosine bases that are adjacent to guanines (CpG [cytosine-phosphate-guanine] bases). Methylation is an example of an epigenetic change, meaning a change that can affect gene expression, and possibly the characteristics of a cell or organism, but that does not involve a change in the underlying genetic sequence. Gene regulation is flexible and responsive, with genes being turned on or off during development and in response to internal and external environmental conditions and stimuli.

Transcription proceeds through the full length of the gene, synthesizing mRNA in a 5′ to 3′ direction. RNA, like DNA, is a sugar-phosphate chain with pyrimidines and purines. In RNA, the sugar is ribose and uracil replaces the thymine found in DNA. The RNA reads off 1 strand of DNA to copy a complementary RNA sequence. A “cap” consisting of 7-methylguanosine is added to the 5′ end of the RNA in a 5′-5′ bond and, for most transcripts, several hundred adenine bases are enzymatically added to the 3′ end after transcription.

mRNA processing occurs in the nucleus and consists of excision of the introns and splicing together of the exons. Specific sequences at the start and end of introns mark the sites where the splicing machinery will act on the transcript. In some cases, there may be tissue-specific
Figure 79-2 Flow of information from DNA to RNA to protein for a hypothetical gene with three exons and two introns. Within the exons, blue indicates the coding sequences. Steps include transcription, RNA processing and splicing, RNA transport from the nucleus to the cytoplasm, and translation. (From Nussbaum RL, McInnis RR, Willard HF, Hamosh A, editors: Thompson & Thompson genetics in medicine, ed 7, Philadelphia, 2007, Saunders/Elsevier, Fig 3.5, p. 31.)

patterns to splicing, so that the same primary transcript can produce multiple distinct proteins.

The processed transcript is next exported to the cytoplasm, where it binds to ribosomes, which are complexes of protein and RNA. The genetic code is then read in triplets of bases, each triplet corresponding with a specific amino acid or providing a signal that terminates translation. The triplet codons are recognized by transfer RNAs that include complementary anticodons and bind the corresponding amino acid, delivering it to the growing peptide. A new amino acid is enzymatically attached to the peptide; each time an amino acid is added, the ribosome moves one triplet codon step along the mRNA. Eventually a stop codon is reached, at which point translation ends and the peptide is released. In some proteins, there are posttranslational modifications, such as attachment of sugars (glycosylation); the protein is then delivered to its destination within or outside the cell by trafficking mechanisms that recognize portions of the peptide.

An emerging layer of complexity and genetic regulation is that of noncoding RNAs. This refers to RNAs that are transcribed from DNA but are not translated into proteins. Noncoding RNAs function in mediating splicing and the processing of coding RNAs in the nucleus and the translation of coding RNAs in ribosomes. The roles of large noncoding RNAs (>200 bp) and short noncoding RNAs (<200 bp) extend beyond these processes to impact a diverse set of biologic functions including regulation of gene expression. For example, microRNAs (miRNAs) are a class of small RNAs that control gene expression in the cell by directly targeting specific sets of coding RNAs by direct RNA–RNA binding. This RNA–RNA interaction can lead to degradation of the target coding RNA or inhibition of translation of the protein specified by that coding RNA. miRNAs, in general, target and regulate several hundred mRNAs.

GENETIC VARIATION

The process of producing protein from a gene is subject to disruption at multiple levels owing to alterations in the coding sequence (Fig. 79-3). Changes in the regulatory region can lead to altered gene expression, including increased or decreased rates of transcription, failure of gene activation, or activation of the gene at inappropriate times or in inappropriate cells. Changes in the coding sequence can lead to substitution of one amino acid for another (missense mutation or nonsynonymous) or creation of a stop codon in the place of an amino acid codon. Overall, missense or nonsense mutations are the most common (~56% of mutations); small deletions or insertions represent approximately 24% of mutations (Table 79-1). Some single-base changes do not affect the amino acid (silent or wobble mutation or synonymous), because there may be several triplet codons that correspond with a single amino acid. Amino acid substitutions can have a profound effect on protein function if the chemical properties of the substituted amino acid are markedly different from the usual one. Other substitutions can have a subtle or no effect on protein function, particularly if the substituted amino acid is chemically similar to the original one.

Genetic changes can also include insertions or deletions. Insertions or deletions of a nonintegral multiple of 3 bases into the coding sequence leads to a frameshift, altering the grouping of bases into triplets. This leads to translation of an incorrect amino acid sequence and often a premature stop to translation. Insertion or deletion of an
Gene, and a 50% decrease in gene function results in an abnormal phenotype. Hence, haploinsufficient phenotypes are, by definition, dominantly inherited. Loss-of-function mutations can also have a dominant negative effect when the abnormal protein product actively interferes with the function of the normal protein product. Both of these situations lead to diseases inherited in a dominant fashion (see Chapter 80). In other cases, loss-of-function mutation must be present in both copies of a gene before an abnormal phenotype results. This situation typically results in diseases inherited in a recessive fashion (see Chapter 80).

Gain-of-function mutations typically cause dominantly inherited diseases. These mutations can result in production of a protein molecule with an increased ability to perform a normal function or they

*Some have been shown to cause aberrant splicing.

can confer a novel property on the protein. The gain-of-function mutation in achondroplasia, the most common of the disproportionate, short-limbed short stature disorders, exemplifies the enhanced function of a normal protein. Achondroplasia results from a mutation in the fibroblast growth factor receptor 3 gene (FGFR3), which leads to activation of the receptor, even in the absence of fibroblast growth factor. In sickle cell disease, an amino acid is substituted into the hemoglobin molecule that has little effect on the ability of the protein to transport oxygen. However, sickle hemoglobin chains have a novel property. Unlike normal hemoglobin, sickle hemoglobin chains aggregate under conditions of deoxygenation, forming fibers that deform the red cells.

In some cases the recognition of a specific constellation of features leads the clinician to suspect a specific microdeletion or microduplication syndrome. Examples of such disorders include Smith-Magenis, DiGeorge, and Williams syndromes. In other cases, the clinician may be alerted to this possibility by an unusually diverse array of clinical features in one patient or the presence of unusual features in a person with a known condition. Owing to the close physical proximity of a series of genes, different deletions involving the short arm of the X chromosome can produce individuals with various combinations of ichthyosis, Kallmann syndrome, ocular albinism, intellectual disability, chondrodysplasia punctata, and short stature.

DNA rearrangements can also take place in somatic cells-meaning that cells do not go on to produce ova or sperm. Rearrangements that occur in lymphoid cells are required for the formation of functional immunoglobulin in B cells and antigen-recognizing receptors on T cells. Large segments of DNA, which code for the variable and the constant regions of either immunoglobulin or the T-cell receptor, are physically joined at a specific stage in the development of an immunocompetent lymphocyte. These rearrangements take place during development of the lymphoid cell lineage in humans and result in the extensive diversity of immunoglobulin and T-cell receptor molecules. It is as a result of this postgermline DNA rearrangement that no 2 individuals, even if identical twins, are really identical, because mature lymphocytes from each will have undergone random DNA rearrangements at these loci.

Studies of the human genome sequence reveal that any 2 individuals differ in about 1 base in 1,000. Some of these differences are silent; some result in changes that explain phenotypic differences (hair or eye color, physical appearance); some have medical significance, causing single-gene disorders such as sickle cell anemia or explaining susceptibility to common pediatric disorders such as asthma. Genetic variants in a single gene that occur at a frequency of >1% in a population are often referred to as polymorphisms. These variations may be silent or subtle or have significant phenotypic effects.
GENOTYPE-PHENOTYPE CORRELATIONS IN GENETIC DISEASE

The term genotype is used to signify the internally coded, heritable information of an individual and can also be used to refer to which particular alternative version (allele) of a gene is present at a specific location (locus) on a chromosome. A phenotype is the observed structural, biochemical, and physiologic characteristics of an individual, determined by the genotype, and can also refer to the observed structural and functional effects of a mutant allele at a specific locus. Many mutations result in predictable phenotypes. In these cases, physicians can predict clinical outcomes and plan appropriate treatment strategies based on a patient's genotype.

The long QT syndrome exemplifies a disorder with predictable associations between a patient's genotype and his or her phenotype (see Chapter 435.5). Long QT syndrome is genetically heterogeneous, meaning that mutations in several different genes can cause the same disorder. The risk for cardiac events (syncope, aborted cardiac arrest, or sudden death) is higher with long QT syndrome mutations involving the KCNQ1 gene (63%) or the KCNH2 gene (46%) than among subjects with mutations in the SCN5A gene (18%). In addition, those with mutations involving KCNQ1 experience most of their episodes during exercise and rarely during rest or sleep. In contrast, individuals with mutations in KCNH2 and SCN5A are more likely to have episodes during sleep or rest, and rarely during exercise. Therefore, mutations in specific genes (genotype) are correlated with specific manifestations (phenotype) of long QT syndrome. These types of relationships are commonly referred to as genotype–phenotype correlations.

Mutations in the fibrillin-1 gene associated with Marfan syndrome represent another example of predictable genotype–phenotype correlations (see Chapter 702). Marfan syndrome is characterized by the combination of skeletal, ocular, and aortic manifestations, with the most devastating outcome being aortic root dissection and sudden death. Sixty-five exons make up the fibrillin-1 gene, and mutations have been found in almost all of these exons. The location of the mutation within the gene (genotype) might play a significant role in determining the severity of the condition (phenotype). Neonatal Marfan syndrome is caused by mutations in exons 24–27 and in exons 31 and 32, whereas milder forms are caused by mutations in exons 59–65 and in exons 37 and 41.

Genotype–phenotype correlations have also been observed in some complications of cystic fibrosis (CF; see Chapter 403). Although pulmonary disease is the major cause of morbidity and mortality, CF is a multisystem disorder that affects not only the epithelia of the respiratory tract but also the exocrine pancreas, intestine, male genital tract, hepatobiliary system, and exocrine sweat glands. CF is caused by mutations in the CF transmembrane conductance regulator (CFTR) gene. More than 1,600 different mutations have been identified. The most common is a deletion of 3 nucleotides that removes the amino acid phenylalanine (F) at the 508th position on the protein (AF508 mutation), which accounts for approximately 70% of all CF mutations and is associated with severe disease. The best genotype–phenotype correlations in CF are seen in the context of pancreatic function, with most common mutations being classified as either pancreatic sufficient or pancreatic insufficient. Persons with pancreatic sufficiency usually have either 1 or 2 pancreatic-sufficient alleles, indicating that pancreatic-sufficient alleles are dominant. In contrast, the genotype–phenotype correlation in pulmonary disease is much weaker, and persons with identical genotypes have wide variations in the severity of their pulmonary disease. This finding may be accounted for in part by genetic modifiers or environmental factors.

There are many disorders in which the effects of mutations on phenotype can be modified by changes in the other allele of the same gene, by changes in specific modifier genes, and/or variations in a number of unspecified genes (genetic background). When sickle cell anemia is coinherited with the gene for hereditary persistence of fetal hemoglobin, the sickle cell phenotypic expression is less severe. Modifier genes in CF can influence the development of congenital meconium ileus, or colonization with Pseudomonas aeruginosa. Modifier genes can also affect the manifestations of Hirschsprung disease, neurofibromatosis type 2, craniosynostosis, and congenital adrenal hyperplasia. The combination of genetic mutations producing glucose-6-phosphate dehydrogenase deficiency and longer versions of the TATAA element in the uridine diphosphate–glucoronoysltransferase gene promoter exacerbates neonatal physiologic hyperbilirubinemia.

HUMAN GENOME PROJECT

A rudimentary genetic map can be made using genetic linkage, which is based on the principle that alleles at 2 genetic loci that are located near each other segregate together in a family unless they are separated by genetic recombination. The frequency of recombination between the loci can be used to estimate the physical distance between points. Some of the first maps of the human genome were linkage maps based on a set of polymorphic genetic loci located along the entire human genome. Linkage analysis is still used to map the location of genetic changes responsible for phenotypic traits and genetic disorders that are inherited in a mendelian fashion.

In contrast to linkage maps, which are based on recombination frequencies, physical maps rely on overlapping DNA fragments to determine the location of loci with respect to one another. Several strategies can be used to create physical maps of a chromosomal region. In one strategy, segments of the region of interest with lengths from hundreds or thousands to a few million base pairs are isolated and placed in microorganisms such as bacteria or yeast. Common regions contained in different organism can then be identified and this information can be used to piece together a map composed of overlapping DNA pieces, each contained in a different microorganism. The pieces contained in each organism can then be sequenced to obtain the DNA sequence of the entire region. An alternative strategy involves breaking the entire genome into random fragments, sequencing the fragments, and then using a computer to order the fragments based on overlapping segments. This whole genome approach in combination with new next-generation sequencing technologies has resulted in a dramatic reduction in the cost of sequencing an individual's entire genome.

Analysis of the human genome has produced some surprising results. The number of genes is still not known precisely but appears to be around 25,000. This is fewer than had been expected and in the same range as many simpler organisms. The number of protein products encoded by the genome is greater than the number of genes. This is a result of the presence of alternative promoter regions, alternative splicing, and posttranslational modifications, which can allow a single gene to encode a number of protein products.

It is also apparent that most of the human genome does not encode protein, with <5% being transcribed and translated, though a much larger percentage may be transcribed without translation. Many transcribed sequences have not been translated but represent genes that encode RNAs that serve a regulatory role. A large fraction of the genome consists of repeated sequences that are interspersed among the genes. Some of these are transposable genetic elements that can move from place to place in the genome. Others are static elements that were expanded and dispersed in the past during human evolution. Other repeated sequences might play a structural role. There are also regions of genomic duplications. Such duplications are substrate for evolution, allowing genetic motifs to be copied and modified to serve new roles in the cell. Duplications can also play a role in chromosomal rearrangement, permitting nonhomologous chromosome segments to pair during meiosis and exchange material. This is another source of evolutionary change and a potential source of chromosomal instability leading to congenital anomalies or cancer. Low copy repeats also play an important role in causing genomic disorders. When low copy repeats flank unique genomic segments, these regions can be duplicated or deleted through a process known as nonallelic homologous recombination.

Availability of the entire human genomic sequence permits the study of large groups of genes, looking for patterns of gene expression or genome alteration. Microarrays permit the expression of thousands of genes to be analyzed on a small glass chip. Increasingly, studies of gene expression are being performed using next generation sequencing.
techniques to obtain information about all of the RNA transcripts in a tissue sample. In some cases the patterns of gene expression provide signatures for particular disease states, such as cancer, or change in response to therapy (Fig. 79-5).

Chapter 80  Patterns of Genetic Transmission
Daryl A. Scott and Brendan Lee

FAMILY HISTORY AND PEDIGREE NOTATION
The family history remains the most important screening tool for pediatricians in identifying a patient’s risk for developing a wide range of diseases, from multifactorial conditions, such as diabetes and attention-deficit disorder, to single-gene disorders such as sickle cell anemia and cystic fibrosis. Through a detailed family history the pediatrician can often ascertain the mode of genetic transmission and the risks to family members. Because not all familial clustering of disease is caused by genetic factors, a family history can also identify common environmental and behavioral factors that influence the occurrence of disease. The main goal of the family history is to identify genetic susceptibility, and the cornerstone of the family history is a systematic and standardized pedigree.

A pedigree provides a graphic depiction of a family’s structure and medical history. It is important when taking a pedigree to be systematic and use standard symbols and configurations (Figs. 80-1 to 80-4) so that anyone can read and understand the information. In the pediatric setting, the proband is typically the child or adolescent who is being evaluated. The proband is designated in the pedigree by an arrow. A 3 to 4-generation pedigree should be obtained for every new patient as an initial screen for genetic disorders segregating within the family. The pedigree can provide clues to the inheritance pattern of these disorders and can aid the clinician in determining the risk to the proband and other family members. The closer the relationship of the proband to the person in the family with the genetic disorder, the greater is the shared genetic complement. First-degree relatives, such as a parent, full sibling, or child, share \( \frac{1}{2} \) their genetic information on average; first cousins share \( \frac{1}{4} \). Sometimes the person providing the family history may mention a distant relative who is affected with a genetic disorder. In such cases a more extensive pedigree may be needed to identify the risk to other family members. For example, a history of a distant maternally related cousin with mental retardation caused by fragile X syndrome can still place a male proband at an elevated risk for this disorder.

MENDELIAN INHERITANCE
There are 3 classic forms of genetic inheritance: autosomal dominant, autosomal recessive, and X-linked. These are referred to as mendelian inheritance forms, after Gregor Mendel, the 19th-century monk whose experiments led to the laws of segregation of characteristics, dominance, and independent assortment. These remain the foundation of single-gene inheritance.

Autosomal Dominant Inheritance
Autosomal dominant inheritance is determined by the presence of 1 abnormal gene on 1 of the autosomes (chromosomes 1-22). Autosomal genes exist in pairs, with each parent contributing 1 copy. In an autosomal dominant trait, a change in 1 of the paired genes has an effect on the phenotype; this can refer to physical manifestations, behavioral characteristics, or differences detectable only through laboratory tests, even though the other copy of the gene is functioning correctly.

The pedigree for an autosomal dominant disorder (Fig. 80-5) demonstrates certain characteristics. The disorder is transmitted in a vertical (parent-to-child) pattern and can appear in multiple generations. This is illustrated by individual I.1 (see Fig. 80-5) passing on the changed gene to II.2 and II.5. An affected individual has a 50% (1 in 2) chance of passing on the deleterious gene in each pregnancy and, therefore, of having a child affected by the disorder. This is referred to as the recurrence risk for the disorder. Unaffected individuals (family members who do not manifest the trait) do not pass the disorder to their children. Males and females are equally affected. Although not a characteristic per se, the finding of male-to-male transmission essentially confirms autosomal dominant inheritance. Vertical transmission can also be seen with X-linked traits. However, because a father passes his Y chromosome to a son, male-to-male transmission cannot be seen with an X-linked trait. Therefore, male-to-male transmission eliminates X-linked inheritance as a possible explanation. Although male-to-male transmission can occur with Y-linked genes as well, there are very few Y-linked disorders compared with thousands having the autosomal dominant inheritance pattern.

Although parent-to-child transmission is a characteristic of autosomal dominant inheritance, for many patients with an autosomal dominant disorder there is no history of an affected family member. There are several possible reasons: First, the patient may represent a new mutation that occurred in the DNA of the egg or sperm that came together to form that individual. Second, many autosomal dominant conditions demonstrate incomplete penetrance, meaning that not all individuals who carry the mutation have phenotypic manifestations. In a pedigree this can appear as a skipped generation, in which an
Instructions:
— Key should contain all information relevant to interpretation of pedigree (e.g., define fill/shading)
— For clinical (non-published) pedigrees include:
  a) name of proband/consultand
  b) family names/initiais of relatives for identification, as appropriate
  c) name and title of person recording pedigree
  d) historian (person relaying family history information)
  e) date of intake/update
  f) reason for taking pedigree (e.g., abnormal ultrasound, familial cancer, developmental delay, etc.)
  g) ancestry of both sides of family
— Recommended order of information placed below symbol (or to lower right)
  a) age; can note year of birth (e.g., b. 1978) and/or death (e.g., d. 2007)
  b) evaluation (see Figure 75-4)
  c) pedigree number (e.g., I-1, I-2, I-3)
— Limit identifying information to maintain confidentiality and privacy

Figure 80-1 Common pedigree symbols, definitions, and abbreviations. (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, J Genet Couns 17:424–433, 2008.)

unaffected individual links 2 affected persons (Fig. 80-6). There are many potential reasons that a disorder exhibits incomplete penetrance, including the effect of modifier genes, environmental factors, gender, and age. Third, individuals with the same autosomal dominant mutation can manifest the disorder to different degrees. This is termed variable expression and is a characteristic of many autosomal dominant disorders. Fourth, some spontaneous genetic mutations occur not in the egg or sperm that forms a child, but rather in a cell in the developing embryo. Such events are referred to as somatic mutations, and because not all cells are affected, the change is said to be mosaic. The
affected, although some traits exhibit different expression in males and females and increased incidence, particularly for rare traits, in the offspring of consanguineous parents. Consanguinity refers to the existence of a relationship by a common ancestor and increases the chance that both parents carry a gene affected by an identical mutation that they inherited. Consanguinity between parents of a child with a suspected genetic disorder implies (but does not prove) autosomal recessive inheritance. Although consanguineous unions are uncommon in Western society, in other parts of the world (southern India, Japan, and the Middle East) they are common; the incidence may be as high as 50%. The risk of a genetic disorder for the offspring of a first-cousin marriage (6-8%) is about double the risk in the general population (3-4%).

Every individual probably has several rare, harmful, recessive mutations. Because most mutations carried in the general population occur.

**Figure 80-2 Pedigree line definitions.** (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, J Genet Couns 17:424–433, 2008.)
at a very low frequency, it does not make economic sense to screen the entire population in order to identify the small number of persons who carry these mutations. As a result, these mutations typically remain undetected unless an affected child is born to a couple who both carry mutations affecting the same gene.

However, in some genetic isolates (small populations separated by geography, religion, culture, or language) certain rare recessive mutations are far more common than in the general population. Even though there may be no known consanguinity, couples from these genetic isolates have a greater chance of sharing mutant alleles inherited from a common ancestor. Screening programs have been developed among some such groups to detect persons who carry common disease-causing mutations and therefore are at increased risk for having affected children. For example, a variety of autosomal recessive conditions are more common among Ashkenazi Jews than in the general population. Couples of Ashkenazi Jewish ancestry should be offered prenatal or preconception screening for Gaucher disease type 1 (carrier rate 1:14), cystic fibrosis (1:25), Tay-Sachs disease (1:25), familial dysautonomia (1:30), Canavan disease (1:40), glycogen storage disease type 1A (1:71), maple syrup urine disease (1:81), Fanconi anemia type C (1:89), Niemann-Pick disease type A (1:90), Bloom syndrome (1:100), mucolipidosis IV (1:120), and possibly neonatal familial hyperinsulinemic hypoglycemia.

The prevalence of carriers of certain autosomal recessive genes in some larger populations is unusually high. In such cases, heterozygote advantage is postulated. For example, the carrier frequencies of sickle cell disease in the African population and of cystic fibrosis in the northern European population are much higher than would be expected from new mutations. It is possible that heterozygous carriers have had an advantage in terms of survival and reproduction over
Figure 80-4 Pedigree symbols of genetic evaluation and testing information. (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, J Genet Couns 17:424–433, 2008.)

**Instructions:**
- E is used for evaluation to represent clinical and/or test information on the pedigree
  - E is to be defined in key/legend
  - If more than one evaluation, use subscript (E₁, E₂, E₃) and define in key
  - Test results should be put in parentheses or defined in key/legend
- A symbol is shaded only when an individual is clinically symptomatic
- For linkage studies, haplotype information is written below the individual. The haplotype of interest should be on left and appropriately highlighted
- Repetitive sequences, trinucleotides, and expansion numbers are written with affected allele first and placed in parentheses
- If mutation known, identify in parentheses

**Figure 80-5 Autosomal dominant pedigree.** Pedigree showing typical inheritance of a form of achondroplasia (FGFR3) inherited as an autosomal dominant trait. Black, affected patients.

**Figure 80-6 Incomplete penetrance.** This family segregates a familial cancer syndrome, familial adenomatous polyposis. Individual II.3 is an obligate carrier, but there are no findings to suggest the disorder. This disorder is nonpenetrant in this individual.
noncarriers. In sickle cell disease, the carrier state might confer some resistance to malaria; in cystic fibrosis, the carrier state has been postulated to confer resistance to cholera or enteropathogenic *Escherichia coli* infections. Population-based carrier screening for cystic fibrosis is recommended for persons of northern European and Ashkenazi Jewish ancestry; population-based screening for sickle cell disease is recommended for persons of African ancestry.

If the frequency of an autosomal recessive disease is known, the frequency of the heterozygote or carrier state can be calculated from the Hardy-Weinberg formula:

\[
p^2 + 2pq + q^2 = 1
\]

where \( p \) is the frequency of one of a pair of alleles and \( q \) is the frequency of the other. For example, if the frequency of cystic fibrosis among white Americans is 1 in 2,500 (\( p^2 \)), then the frequency of the heterozygote (2pq) can be calculated: If \( p^2 = 1/2,500 \), then \( p = 1/50 \) and \( q = 49/50; 2pq = 2 \times (1/50) \times (49/50) = 98/2500 \) or 3.92%.

**Pseudodominant Inheritance**

Pseudodominant inheritance refers to the observation of apparent dominant (parent to child) transmission of a known autosomal recessive disorder (Fig. 80-8). This occurs when a homozygous affected individual has a partner who is a heterozygous carrier, and it is most likely to occur for relatively common traits, such as sickle cell anemia or nonsyndromic autosomal recessive hearing loss because of mutations in *GJB2*, the gene that encodes Connexin 26.

**X-Linked Inheritance**

Characteristics of X-linked inheritance (Fig. 80-9) include the following:

- Males are more commonly and more severely affected than females.
- Female carriers are generally unaffected, or if affected, they are affected more mildly than males.
- Female carriers have a 25% risk for having an affected son, a 25% risk for a carrier daughter, and a 50% chance of having a child that does not inherit the mutated X-linked gene.
- Affected males have carrier daughters and unaffected sons because they pass their X chromosome to all of their daughters and their Y chromosome to all of their sons. Male-to-male transmission excludes X-linkage but is seen with autosomal dominant and Y-linked inheritance.

A female occasionally exhibits signs of an X-linked trait similar to a male. This occurs rarely owing to homozygosity for an X-linked trait or the presence of a sex chromosome abnormality (45,X or 46,XY female) or skewed or nonrandom X-inactivation. X chromosome inactivation occurs early in development and involves random and irreversible inactivation of most genes on one X chromosome in female cells (Fig. 80-10). In some cases, a preponderance of cells inactivates the same X chromosome, resulting in phenotypic expression of an X-linked mutation if it resides on the active chromosome. This can occur owing to chance, selection against cells that have inactivated the X chromosome carrying the normal gene, or X chromosome abnormalities that result in inactivation of the X chromosome carrying the normal gene.

Some X-linked disorders are inherited in an X-linked dominant fashion in which female carriers typically manifest abnormal findings. An affected man will have only affected daughters and unaffected sons, and half of the offspring of an affected woman will be affected (Fig. 80-11). Some X-linked dominant conditions are lethal in a high percentage of males. An example is incontinentia pigmenti (see Chapter 596.7). The pedigree shows only affected females and an overall ratio of 2:1 females to males with an increased number of miscarriages (Fig. 80-12).

**Y-LINKED INHERITANCE**

There are few Y-linked traits. These demonstrate only male-to-male transmission, and only males are affected (Fig. 80-13). Most Y-linked genes are related to male sex determination and reproduction and are associated with infertility. Therefore, it is rare to see familial transmission of a Y-linked disorder. However, advances in assisted reproductive technologies might make it possible to have familial transmission of male infertility.

Of special note are the pseudoautosomal regions on the Y chromosome that have homology that is shared by both Xp and Yp. Very few genes reside in this region. One of the few is *SHOX*. Heterozygous *SHOX* mutations cause Leri-Weil dyschondrosteosis, a rare skeletal dysplasia that involves bilateral bowing of the forearms with
dislocations of the ulna at the wrist and generalized short stature. Homozygous mutations cause the much more severe Langer mesomelic dwarfism.

DIGENIC INHERITANCE

Digenic inheritance explains the occurrence of retinitis pigmentosa (RP) in children of parents who each carry a mutation in a different RP-associated gene. Both parents have normal vision, as would be expected, but their offspring who are double heterozygotes—having inherited both mutations—develop RP. Digenic pedigrees (Fig. 80-14) can exhibit characteristics of both autosomal dominant (vertical transmission) and autosomal recessive inheritance (1 in 4 recurrence risk). For example, a couple in which the 2 unaffected partners are carriers for mutation in 2 different RP-associated genes that show digenic inheritance have a 1 in 4 risk of having an affected child similar to what is seen in autosomal recessive inheritance. However, their affected

Figure 80-10 X-inactivation. Black marks the active X chromosome. Color of the cell represents its active X chromosome is paternally (X_p, blue) or maternally (X_m, pink) derived.

Figure 80-11 Pedigree pattern demonstrating X-linked dominant inheritance. Note there is no father-to-son transmission in this situation, and hemizygosity (i.e., X-linked gene in a male) is not lethal. In some X-linked dominant conditions, X-linked males have a more severe phenotype and might not survive. In that case, only females manifest the disease (see Fig. 80-12).

Figure 80-12 Pedigree of an X-linked dominant disorder with male lethality, such as incontinentia pigmenti.

Part X

Human Genetics

**Figure 80-14 Digenic pedigree.** Here, the disease alleles are a and b and they reside on distinct genetic loci or genes. For a person to have the disease, heterozygosity for mutant alleles in both genes (A/a;B/b) is required.

![Digenic Pedigree](image)

children, and affected children in subsequent generations, have a 1 in 4 risk of transmitting both mutations to their offspring, who would be affected (vertical transmission).

**PSEUDOGENETIC INHERITANCE AND FAMILIAL CLUSTERING**

Sometimes nongenetic reasons for the occurrence of a particular disease in multiple family members can produce a pattern that mimics genetic transmission. These nongenetic factors can include identifiable environmental factors, teratogenic exposures, or as yet undefined factors. Examples of identifiable factors might include multiple siblings in a family having asthma as a result of exposure to cigarette smoke from their parents or having failure to thrive, developmental delay, and unusual facial appearance caused by exposure to alcohol during pregnancy.

In some cases the disease is sufficiently common in the general population that some familial clustering occurs simply by chance. Breast cancer affects 11% of all women, and it is possible that several women in a family will develop breast cancer even in the absence of a genetic predisposition. However, hereditary breast cancer associated with mutations in BRCA1 and BRCA2 should be suspected in any individual who has a personal history of breast cancer with onset before age 50 yr, early-onset breast and ovarian cancer at any age, bilateral or multifocal breast cancer, a family history of breast cancer or breast and ovarian cancer consistent with autosomal dominant inheritance, and/or a personal or family history of male breast cancer.

**NONTRADITIONAL INHERITANCE**

Some genetic disorders are inherited in a manner that does not follow classical Mendelian patterns. Nontraditional inheritance includes mitochondrial disorders, triplet repeat expansion diseases, and imprinting defects.

**Mitochondrial Inheritance**

An individual's mitochondrial genome is entirely derived from the mother because sperm contain few mitochondria, which are typically shed upon fertilization. It follows that mitochondrial disorders exhibit maternal inheritance. A woman with a mitochondrial genetic disorder can have affected offspring of either sex, but an affected father cannot pass on the disease to his offspring (Fig. 80-15). Mitochondrial DNA mutations are often deletions or point mutations; overall, 1:400 people has a maternally inherited pathogenic mitochondrial DNA mutation.

In individual families, mitochondrial inheritance may be difficult to distinguish from autosomal dominant or X-linked inheritance, but in many cases, paying close attention to the sex of the transmit-

ting and nontransmitting parents can suggest a mitochondrial basis (Table 80-1).

The mitochondria are the cell's suppliers of energy, and it is not surprising that the organs that are most affected by the presence of abnormal mitochondria are those that have the greatest energy requirements, such as the brain, muscle, heart, and liver (see Chapters 87.4, 361, 598.2, and 611.4). Common manifestations include developmental delay, seizures, cardiac dysfunction, decreased muscle strength and tone, and hearing and vision problems. Examples of mitochondrial disorders include MELAS (myopathy, encephalopathy, lactic acidosis, and strokelike episodes), MERRF (myoclonic epilepsy associated with ragged red fibers), and Kearns-Sayre syndrome (ophthalmoplegia, pigmentary retinopathy, and cardiomyopathy) (see Chapter 598.2 and 611.4).

Mitochondrial diseases can be highly variable in clinical manifestation. This is partly because cells can contain multiple mitochondria, each bearing several copies of the mitochondrial genome. Thus, a cell can have a mixture of normal and abnormal mitochondrial genomes, which is referred to as heteroplasmasy. Unequal segregation of mitochondria carrying normal and abnormal genomes and replicative advantage can result in varying degrees of heteroplasmasy in the cells of an affected individual, including the individual ova of an affected female. Because of this, a mother may be asymptomatic and yet have children who are severely affected. The level of heteroplasmasy at which disease symptoms typically appear can also vary based on the type of mitochondrial mutation. Detection of mitochondrial genome mutations can require sampling of the affected tissue for DNA analysis; testing for mitochondrial DNA mutations may in some tissues, such as blood, be inadequate because the mutation may be found primarily in affected tissues such as muscle.

**Triplet Repeat Expansion Disorders**

Triplet repeat expansion disorders are distinguished by the special dynamic nature of the disease-causing mutation. Triplet repeat expansion disorders include fragile X syndrome, myotonic dystrophy, Huntington disease, spinocerebellar ataxias, and several others (Table 80-2). These disorders are caused by expansion in the number of 3-bp repeats. The fragile X gene, FMR1, normally has 5-40 CGG triplets. An error in replication can result in expansion of that number to a level in the gray zone between 41 and 58 repeats, or to a level referred to as premutation, which comprises 59-200 repeats. Some male carriers of the premutation develop fragile X-associated tremor/ataxia syndrome (FXTAS) as adults, and female carriers of the premutation are at risk for fragile X-associated primary ovarian insufficiency (FXPOI). Persons with a premutation are also at risk for having the gene expand further in subsequent meiosis, hence crossing into the range of full mutation in offspring. In fragile X, the threshold for clinical diagnosis is above 200 repeats. With this number of repeats, the FMR1 gene becomes hypermethylated, and protein production is lost.

Some triplet expansions associated with other genes can cause disease through a mechanism other than decreased protein production. In Huntington disease, the expansion causes the gene product...

*Continued*
to have a new, toxic effect on the neurons of the basal ganglia. For most triplet-repeat disorders, there is a clinical correlation to the size of the expansion, with a greater expansion causing more severe symptoms and/or earlier age of onset for the disease. The observation of increasing severity of disease and early age at onset in subsequent generations is termed genetic anticipation and is a defining characteristic of many triplet-repeat expansion disorders (Fig. 80-16).

**Genetic Imprinting**

The 2 copies of most autosomal genes are functionally equivalent. However, in some cases only 1 copy of a gene is transcribed and the other copy is silenced. This gene silencing is typically associated with methylation of DNA, which is an epigenetic modification, meaning it does not change the nucleotide sequence of the DNA (Fig. 80-17). In imprinting, gene expression depends on the parent of origin of the chromosome (see Chapter 81.8). Imprinting disorders result from an imbalance of active copies of a given gene, which can occur for several reasons. Prader-Willi and Angelman syndromes, two distinct disorders associated with developmental impairment, are illustrative. Both

Patterns of Genetic Transmission

DNA methylation patterns within a cell are characteristic of that cell type. Cell type-specific and tissue-specific DNA methylation are illustrated by organ-to-organ variations in the clusters of methylated CpGs within the same individual. Despite overall consistency in tissue-specific DNA methylation patterns, variations in these patterns exist among different individuals. Methylated CpGs are indicated by a filled circle and unmethylated CpGs by an open circle. SNPs are indicated by the corresponding base. (Redrawn from Brena RM, Huang THM, Plass C: Toward a human epigenome, Nat Genet 38:1359–1360, 2006.)

Multifactorial inheritance refers to traits that are caused by a combination of inherited, environmental, and stochastic factors. There is a similar rate of recurrence among all 1st-degree relatives (parents, siblings, offspring of the affected child). It is unusual to find a substantial increase in risk for relatives related more distantly than 2nd degree to the index case. The risk of recurrence is related to the incidence of the disease. Some disorders have a sex predilection, as indicated by an unequal male:female incidence. Pyloric stenosis, for example, is more common in males, whereas congenital dislocation of the hips is more common in females. Where there is an altered sex ratio, the risk is higher for the relatives of an index case whose gender is less commonly affected than relatives of an index case of the more commonly affected gender. For example, the risk to the son of an affected female is 20%, compared with the 5% risk for the son of an affected male.

Multifactorial traits differ from polygenic inheritance, which refers to traits that result from the additive effects of multiple genes. Multifactorial traits segregate within families but do not exhibit a consistent or recognizable inheritance pattern. Characteristics include the following:

- There is a similar rate of recurrence among all 1st-degree relatives (parents, siblings, offspring of the affected child). It is unusual to find a substantial increase in risk for relatives related more distantly than 2nd degree to the index case.
- The risk of recurrence is related to the incidence of the disease.
- Some disorders have a sex predilection, as indicated by an unequal male:female incidence. Pyloric stenosis, for example, is more common in males, whereas congenital dislocation of the hips is more common in females. Where there is an altered sex ratio, the risk is higher for the relatives of an index case whose gender is less commonly affected than relatives of an index case of the more commonly affected gender. For example, the risk to the son of an affected female with infantile pyloric stenosis is 18%, compared with the 5% risk for the son of an affected male. An affected female presumably has a greater genetic susceptibility, which she can then pass on to her offspring.
- The likelihood that both identical twins will be affected with the same malformation is less than 100% but much greater than the chance that both members of a nonidentical twin pair will be affected. This is in contrast with the pattern seen in mendelian...
inheritance, in which identical twins almost always share fully penetrant genetic disorders.

- The risk of recurrence is increased when multiple family members are affected. A simple example is that the risk of recurrence for unilateral cleft lip and palate is 4% for a couple with 1 affected child and increases to 9% with 2 affected children. It is sometimes difficult to distinguish between a multifactorial and mendelian etiology in families with multiple affected individuals.

- The risk of recurrence may be greater when the disorder is more severe. For example, an infant who has long-segment Hirschsprung disease has a greater chance of having an affected sibling than the infant who has short-segment Hirschsprung disease.

There are 2 types of multifactorial traits. One exhibits continuous variation, with “normal” individuals falling within a statistical range—often defined as having a value 2 SDs above and/or below the mean—and “abnormals” falling outside that range. Examples include such traits as intelligence, blood pressure, height, and head circumference. For many of these traits, offspring values can be estimated based on a modified average of their parental values, with nutritional and environmental factors playing an important role.

With other multifactorial traits, the distinction between normal and abnormal is based on the presence or absence of a particular trait. Examples include pyloric stenosis, neural tube defects, congenital heart defects, and cleft lip and cleft palate. Such traits follow a threshold model (see Fig. 80-15). A distribution of liability because of genetic and nongenetic factors is postulated in the population. Individuals who exceed a threshold liability develop the trait, and those below the threshold do not.

The balance between genetic and environmental factors is demonstrated by neural tube defects. Genetic factors are implicated by the increased recurrence risk for parents of an affected child compared with the general population, yet the recurrence risk is about 3%, less than what would be expected if the trait was caused by a single, fully penetrant mutation. The role of nongenetic environmental factors can be seen in the fact that the recurrence risk can be lowered by up to 87% if the mother-to-be takes 4 mg of folic acid per day starting 3 mo before conception.

Many adult-onset diseases behave as if they are caused by multifactorial inheritance. Diabetes, coronary artery disease, and schizophrenia are examples.

Figure 80-18 The progressive decrease in the genetic load contributing to the development of a disease creates a smooth transition in the distribution of illnesses on an etiologic diagram. In theory, no diseases are completely free from the influence of both genetic and environmental factors. (From Bomprezzi R, Kovanen PE, Martin R: New approaches to investigating heterogeneity in complex traits, J Med Genet 40:553–559, 2003. Reproduced with permission from the BMJ Publishing Group.)

Bibliography is available at Expert Consult.

Clinical cytogenetics is the study of chromosomes: their structure, function, inheritance, and abnormalities. Chromosome abnormalities are very common and occur in approximately 1-2% of live births, 5% of stillbirths, and 50% of early fetal losses in the 1st trimester of pregnancy (Table 81-1). Chromosome abnormalities are more common among persons with intellectual disability and they play a significant role in the development of some neoplasias.

Chromosome analyses are indicated in persons presenting with multiple congenital anomalies, dysmorphic features, and/or intellectual disability. The specific indications for studies include advanced maternal age (>35 yr) or multiple abnormalities on fetal ultrasound (prenatal testing), multiple congenital anomalies, unexplained growth restriction in the fetus or postnatal problems in growth and development, ambiguous genitalia, unexplained intellectual disability with or without associated anatomic abnormalities, primary amenorrhea or infertility, recurrent miscarriages (≥3) or prior history of stillbirths and neonatal deaths, a 1st-degree relative with a known or suspected structural chromosome abnormality, clinical findings consistent with a known anomaly, some malignancies, and chromosome breakage syndromes (e.g., Bloom syndrome, Fanconi anemia).

81.1 Methods of Chromosome Analysis
Carlos A. Bacino and Brendan Lee

Cytogenetic studies are usually performed on peripheral blood lymphocytes, although cultured fibroblasts may also be used. Prenatal (fetal) chromosome studies are performed with cells obtained from the amniotic fluid, chorionic villus tissue, and fetal blood or, in the case of preimplantation diagnosis, by analysis of a blastomere. Cytogenetic studies of bone marrow have an important role in tumor surveillance, particularly among patients with leukemia. These are useful to determine induction of remission and success of therapy or, in some cases, the occurrence of relapses.

Chromosome anomalies include abnormalities of number and structure and are the result of errors during cell division. There are 2 types of cell division: mitosis, which occurs in most somatic cells, and meiosis, which is limited to the germ cells. In mitosis, 2 genetically identical daughter cells are produced from a single parent cell. DNA duplication has already occurred during interphase in the S phase of the cell cycle (DNA synthesis). Therefore, at the beginning of mitosis the chromosomes consist of 2 double DNA strands joined together at the centromere known as sister chromatids. Mitosis can be divided into 4 stages: prophase, metaphase, anaphase, and telophase. Prophase is characterized by condensation of the DNA. Also during prophase, the nuclear membrane and the nucleolus disappear and the mitotic spindle forms. In metaphase, the chromosomes are maximally compacted and are clearly visible as distinct structures. The chromosomes align at the center of the cell and spindle fibers connect to the centromere of each chromosome and extend to centrioles at the 2 poles of the mitotic figure. In anaphase, the chromosomes divide along their longitudinal axes to form 2 daughter chromatids, which then migrate to opposite poles of the cell. Telophase is characterized by formation of 2 new nuclear membranes and nucleoli, duplication of the centrioles, and cytoplasmic cleavage to form the 2 daughter cells.

Meiosis begins in the female oocyte during fetal life and is completed years to decades later. In males, it begins in a particular spermatogonial cell sometime between adolescence and adult life and is completed in a few days. Meiosis is preceded by DNA replication so that at the outset each of the 46 chromosomes consists of 2 chromatids. In meiosis, a diploid cell (2n = 46 chromosomes) divides to form haploid cells (n = 23 chromosomes). Meiosis consists of 2 major rounds of cell division. In meiosis I, each of the homologous chromosomes pair precisely so that genetic recombination, involving exchange between 2 DNA strands (crossing over), can occur. This results in a reshuffling of the genetic information on the recombined chromosomes and allows further genetic diversity. Each daughter cell then receives 1 of each of the 23 homologous chromosomes. In meiosis II, the daughter cells receive most of the cytoplasm and becomes the egg, whereas the other smaller cell becomes the first polar body. Meiosis II is similar to a mitotic division but without a preceding round of DNA duplication (replication). Each of the 23 chromosomes divides longitudinally, and the homologous chromatids migrate to opposite poles of the cell. This produces 4 spermatogonia in males, or an egg cell and a second polar body in females, each with a haploid (n = 23) set of chromosomes. Consequently, meiosis fulfills 2 crucial roles: It reduces the chromosome number from diploid (46) to haploid (23) so that upon fertilization a diploid number is restored, and it allows genetic recombination.

Two errors of cell division commonly occur during meiosis or mitosis, and either can result in an abnormal number of chromosomes. The first is nondisjunction, in which 2 chromosomes fail to separate during meiosis and thus migrate together into 1 of the new cells, producing 1 cell with 2 copies of the chromosome and another with no copy. The second is anaphase lag, in which a chromatin or chromosome is lost during mitosis because it fails to move quickly enough during anaphase to become incorporated into 1 of the new daughter cells (Fig. 81-1).

For chromosome analysis, cells are cultured (for varying periods depending on cell type), with or without stimulation, and then artificially arrested in mitosis during metaphase (or prometaphase), later on subjected to a hypotonic solution to allow disruption of the nuclear cell membrane and proper dispersion of the chromosomes for analysis, fixed, banded, and finally stained. The most commonly used banding and staining method is the G-banding (G-bands trypsin Giemsa), also known as G banding, which produces a unique combination of dark (G-positive) and light (G-negative) bands that permits recognition of all individual 23 chromosome pairs for analysis. Other banding techniques, such as Q-banding using quinacrine, reverse banding (R-banding) using acridine orange, and C-banding (constitutive heterochromatin) using barium hydroxide, are available for use in certain circumstances but are losing ground to molecular technologies. Metaphase chromosome spreads are first evaluated microscopically, and then their images are photographed or captured by a video camera and stored on a computer to be later analyzed. Humans have 46 chromosomes or 23 pairs, which are classified as autosomes for chromosomes 1 to 22, and the sex chromosomes, often referred to as sex complement: XX for females and XY for males. The homologous chromosomes from a metaphase spread can then be paired and arranged systematically to assemble a karyotype according to well-defined standard conventions like those established by International
System for Human Cytogenetic Nomenclature (ISCN), with chromosome 1 being the largest and 22 the smallest. According to nomenclature, the description of the karyotype includes the total number of chromosomes followed by the sex chromosome constitution. A normal karyotype is 46,XX for females and 46,XY for males (Fig. 81-2). Abnormalities are noted after the sex chromosome complement.

Although the internationally accepted system for human chromosome classification relies largely on the length and banding pattern of each chromosome, the position of the centromere relative to the ends of the chromosome also is a useful distinguishing feature (Fig. 81-3). The centromere divides the chromosome in 2, with the short arm designated as the **p arm** and the long arm designated as the **q arm**. A plus or minus sign before the number of a chromosome indicates that there is an extra or missing chromosome, respectively. **Table 81-2** lists some of the abbreviations used for the descriptions of chromosomes and their abnormalities. A metaphase chromosome spread usually shows 450-550 bands. Prophase and prometaphase chromosomes are longer, are less condensed, and often show 550-850 bands. High-resolution analysis is useful for detecting subtle chromosome abnormalities that might otherwise go unrecognized.

Molecular techniques such as fluorescence in situ hybridization (FISH) and array comparative genomic hybridization studies (conventional CGH and array CGH [aCGH]) have filled a significant void for diagnosing cryptic chromosomal abnormalities. These techniques identify subtle abnormalities that are often below the resolution of standard cytogenetic studies.

**FISH** is used to identify the presence, absence, or rearrangement of specific DNA segments and is performed with gene- or region-specific DNA probes. Several FISH probes are used in the clinical setting: unique sequence or single-copy probes, repetitive-sequence probes (alpha satellites in the pericentromeric regions), and multiple-copy probes (chromosome specific or painting) (Fig. 81-4A and B). FISH involves using a unique known DNA sequence or probe labeled with a fluorescent dye that is complementary to the studied region of disease interest. The labeled probe is exposed to the DNA on a microscope slide, typically metaphase or interphase chromosomal DNA. When the probe pairs with its complementary DNA sequence, it can then be visualized by fluorescence microscopy (Fig. 81-5). In metaphase chromosome spreads, the exact chromosomal

![Figure 81-3](image-url)  
**Figure 81-3** Example of different chromosome types according to the position of the centromere. On the left is a chromosome pair with the centromere equidistant from the short and long arm (also known as metacentric). In the center is a chromosome 11 pair that is submetacentric. On the right is a chromosome 13 pair that is an example of an acrocentric chromosome. Acrocentric chromosomes contain a very small short arm, stalks, and satellite DNA. The black arrow indicates the position of the centromere. The blue arrow shows the long arm of a chromosome. The red arrow shows the short arm of a chromosome. The green arrow highlights the satellite region, which is made of DNA repeats. The light area between the short arm and the satellite is known as the stalk.

**Figure 81-4** A, FISH analysis of interphase peripheral blood cells from a patient with Down syndrome using a chromosome 21-specific probe. The 3 red signals mark the presence of 3 chromosomes 21. B, FISH analysis of a metaphase chromosome spread from a clinically normal individual using a whole-chromosome paint specific for chromosome 5. Both chromosomes 5 are completely labeled (yellow) along their entire length. C, FISH on metaphase cells using a unique sequence probe that hybridizes to the elastin gene on chromosome 7q11.23, inside the Williams syndrome critical region. The elastin probe is labeled in red, and a control probe on chromosome 7 is labeled in green. The left image shows normal hybridization to chromosome 7, with 2 signals for the elastin region and 2 for the control probe. The right image shows a normal chromosome on the right with control and elastin signals, and a deleted chromosome 7 on the left, evidenced by a single signal for the control probe. This image corresponds to a patient with a Williams syndrome region deletion.
Figure 81-5 FISH involves denaturation of double-stranded DNA as present in metaphase chromosomes or interphase nuclei on cytogenetic slide preparations (A) into single-stranded DNA (B). The slide-bound (in situ) DNA is then renatured or reannealed in the presence of excess copies of a single-stranded, fluorochrome-labeled DNA base-pair sequence or probe (C). The probe anneals or “hybridizes” to sites of complementary DNA sequence (D) within the chromosomal genome. Probe signal is visualized and imaged on the chromosome by fluorescent microscopy. (From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In Hyme HE, Greydanus D, editors: Genetic disorders in adolescents: state of the art reviews. Adolescent medicine, Philadelphia, 2002, Hanley and Belfus, pp. 305–313.)

Figure 81-4, cont’d D, FISH in interphase cells using DNA probes that hybridize to repetitive α-satellite sequences in the pericentromeric region for the sex chromosomes. Left, interphase cells with 2 signals, 1 labeled in red for the X chromosome and green for the Y chromosome, consistent with a normal male chromosome complement. Right, interphase cell showing 2 red signals for the X chromosome, compatible with a normal female chromosome complement.
location of each probe copy can be documented and often the number of copies (deletions, duplications) of the DNA sequence as well. When the interrogated segments (as in genomic duplications) are close together, only interphase cells can accurately determine the presence of 2 or more copies or signals since in metaphase cells, some duplications might falsely appear as a single signal.

With high-resolution chromosome analysis it is very difficult to recognize deletions of <5 million bp (5 Mbp); FISH can reliably detect deletions as small as 50-200 kb of DNA. This has allowed the clinical characterization of a number of microdeletion syndromes. Other probes hybridize to repetitive sequences located to the pericentromeric regions. Pericentromeric probes are still widely used for the rapid identification of certain trisomies in interphase cells of blood smears, or even in the rapid analysis of prenatal samples from cells obtained through amniocentesis. Such probes are available for chromosomes 13, 18, and 21 and for the sex pair X and Y (see Fig. 81-4C and D). With regards to the detection of genomic disorders, FISH is no longer the first line of testing, and its role has also mostly changed to the confirmation of microarray findings.

Spectral karyotyping and multicolor FISH are similar molecular cytogenetic techniques that use 24 different chromosome painting probes and 5 fluorochromes to simultaneously visualize every chromosome. CGH is a molecular-based technique that involves differentially labeling the patient's DNA with a fluorescent dye (green) and a normal reference DNA with another fluorescent dye (red; Fig. 81-6). Equal amounts of the 2-label DNA samples are mixed and then used as a painting probe for FISH with normal metaphase chromosomes. The ratio of green:red fluorescence is measured along each chromosome. Regions of amplification of the patient's DNA display an excess of green fluorescence, and regions of loss show excess red fluorescence. If the patient's and the control DNA are equally represented, the green:red ratio is 1:1 and the chromosomes appear yellow.

A modified version of this technology, aCGH, uses DNA spotted onto a slide or microarray grid. In this case, instead of metaphase

---

**Figure 81-6** An example of a cryptic microdeletion at a translocation breakpoint of an apparently balanced translocation in a patient with DD and growth defect. A, Partial karyotype shows t(15;22)(q26.1;q11.2). B, FISH with clones 2O19 (green) and 354M14 (red) at 15q26.1; arrows indicate signals only present on the normal chromosome 15, suggesting a deletion on the der(15). C, Two-color aCGH with dye swap with 244 K oligo probes; arrowhead indicates a 3.3-Mbp deletion at chromosome 15q26.1-q26.2, arrow points to the close-up view of the deletion. (From Li MM, Andersson HC: Clinical application of microarray-based molecular cytogenetics: an emerging new era of genomic medicine, J Pediatr 155:311-317, 2009, with permission of the authors and publisher.)
chromosomes, segments of DNA are represented by oligonucleotides (short DNA segments) distributed in a microarray that resembles the chromosomes in a metaphase. The detection is currently possible at the single exon resolution level depending on the arrays employed. There are many advantages of aCGH. It can test all critical disease-causing regions in the genome at once; FISH requires the clinical knowledge and tests only 1 area at a time. aCGH can detect duplications and deletions not currently recognized as recurrent disease-causing regions probed by FISH. aCGH can detect single and contiguous gene deletion syndromes. aCGH does not always require cell culture to generate sufficient DNA, something that may be important in the context of prenatal testing because of timing. There are disadvantages to aCGH: It does not detect balanced translocations, inversions, or very low-levels of mosaicism.

There are different types of aCGH; some of them are more targeted while others have whole-genome coverage. Targeted aCGH is an effective and efficient technique for detecting clinically known cryptic chromosomal aberrations, which are typically associated with known disease phenotypes; many of these arrays have expanded detection to areas potentially susceptible to recurring deletion or duplication.

Whole-genome arrays target the entire genome. The advantage of this latter technique is that it allows better and denser coverage of the entire genome in evenly spaced portions; its disadvantage is that interpretation of deletions or duplications may be difficult if it involves areas not previously known to be involved in disease. There is a new type of array being used in the clinical setting and that is the so-called single nucleotide polymorphism (SNP) array. SNPs are polymorphic variations between 2 nucleotides and when analyzed in massive parallel fashion, they can provide very valuable clinical information. Several million SNPs normally occur in the human genome. SNP arrays can help with the detection of uniparental disomies as well as consanguinity. Many arrays currently used in clinical practice combine the use of oligonucleotides for the detection of copy number variations in conjunction with SNPs.

There are many copy number variations causing deletion or duplication in the human genome. Thus, most detected genetic abnormalities, unless associated with very well-known clinical phenotypes, require parental investigations because a detected copy number variation that is inherited might turn out to be an incidental polymorphic variant. A de novo abnormality (i.e., one found only in the child and not the parents) is often more significant if it is associated with an abnormal phenotype found only in the child and if it involves genes with important functions. aCGH is a very valuable technology alone or when combined with FISH and conventional chromosome studies (Fig. 81-7).

Bibliography is available at Expert Consult.

81.2 Down Syndrome and Other Abnormalities of Chromosome Number
Brendan Lee

ANEUPLOIDY AND POLYPLOIDY
Human cells contain a multiple of 23 chromosomes (n = 23). A haploid cell (n) has 23 chromosomes (typically in the ovum or sperm). If a cell’s chromosomes are an exact multiple of 23 (46, 69, 92 in humans), those cells are referred to as euploid. Polyploid cells are euploid cells with more than the normal diploid number of 46 (2n) chromosomes: 3n, 4n. Polyploid conceptions are usually not viable, but the presence of mosaicism with a karyotypically normal line can allow survival. Mosaicism is an abnormality defined as the presence of 2 or more cell lines in a single individual. Polyploidy is a common abnormality seen in 1st-trimester pregnancy losses. Trioid cells are those with 3 haploid sets of chromosomes (3n) and are only viable in a mosaic form. Triploid infants can be liveborn but do not survive long. Triploidy is often the result of fertilization of an egg by 2 sperm (dispermy). Failure of 1 of the meiotic divisions, resulting in a diploid egg or sperm, can also result in triploidy. The phenotype of a triploid conception depends on the origin of the extra chromosome set. If the extra set is of maternal origin, it results in a partial hydatidiform mole with poor embryonic development, but triploid conceptions that have an extra set of maternal chromosomes results in severe embryonic retardation with a small fibrotic placenta that is typically spontaneously aborted.

Abnormal cells that do not contain a multiple of haploid number of chromosomes are termed aneuploid cells. Aneuploidy is the most common and clinically significant type of human chromosome abnormality, occurring in at least 3–4% of all clinically recognized pregnancies. Monosomies occur when only 1, instead of the normal 2, of a given chromosome is present in an otherwise diploid cell. In humans,
Bibliography

Petherick A: Cell-free DNA screening for trisomy is rolled out in Israel, Lancet 382:846, 2013.
most autosomal monosomies appear to be lethal early in development, and survival is possible in mosaic forms or by means of chromosome rescue (restoration of the normal number by duplication of single monosomic chromosome). An exception to this rule is monosomy for the X chromosome (45,X), seen in Turner syndrome; it has been estimated that the majority of 45,X conceptuses are lost early in pregnancy for as yet unexplained reasons.

The most common cause of aneuploidy is nondisjunction, the failure of chromosomes to disjoin normally during meiosis (see Fig. 81-1). Nondisjunction can occur during meiosis I or II or during mitosis. After meiotic nondisjunction, the resulting gamete either lacks a chromosome or has 2 copies instead of 1 normal copy, resulting in a monosomic or trisomic zygote, respectively.

Trisomy is characterized by the presence of 3 chromosomes, instead of the normal 2, of any particular chromosome. Trisomy is the most common form of aneuploidy. Trisomy can occur in all cells or it may be mosaic. Most individuals with trisomy exhibit a consistent and specific phenotype depending on the chromosome involved.

FISH is a technique that can be used for rapid diagnosis in the prenatal detection of common fetal aneuploidies including chromosomes 13, 18, and 21, as well as sex chromosomes (see Fig. 81-4C and D).

The most common numerical abnormalities in liveborn children include trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), and sex chromosomal aneuploidies: Turner syndrome (usually 45,X), Klinefelter syndrome (47,XXY), 47,XXX, and 47,XY,Y. By far the most common type of trisomy in liveborn infants is trisomy 21 (47,XX,+21 or 47,XY,+21) (see Table 81-1). Trisomy 18 and trisomy 13 are relatively less common and are associated with a characteristic set of congenital anomalies and severe intellectual disability (Table 81-3). The occurrence of trisomy 21 and other trisomies increases with advanced maternal age (≥35 yr). Owing to this increased risk, women who are ≥35 yr at the time of delivery should be offered genetic counseling and prenatal diagnosis (including serum screening, ultrasonography, and amniocentesis or chorionic villus sampling; see Chapter 96).

### DOWN SYNDROME

Trisomy 21 is the most common genetic cause of moderate intellectual disability. The incidence of Down syndrome in live births is approximately 1 in 733; the incidence at conception is more than twice that rate; the difference is accounted by early pregnancy losses. In addition to cognitive impairment, Down syndrome is associated with congenital anomalies and characteristic dysmorphic features (Figs. 81-8 and 81-9; Table 81-4). Although there is variability in the clinical features, the constellation of phenotypic features is fairly consistent and permits clinical recognition of trisomy 21. Affected individuals are more prone to congenital heart defects (50%) such as atrioventricular septal defects, ventricular septal defects, isolated secundum atrial septal defects,

patent ductus arteriosus, and tetralogy of Fallot. Congenital and acquired gastrointestinal anomalies and hypothyroidism are common (Table 81-5). Other abnormalities include megakaryoblastic leukemia, immune dysfunction, diabetes mellitus, and problems with hearing and vision (Table 81-5). Alzheimer disease–like dementia is a known complication that occurs as early as the 4th decade and has an incidence 2-3 times higher than sporadic Alzheimer disease. Most males with Down syndrome are sterile, but some females have been able to reproduce, with a 50% chance of having trisomy 21 pregnancies. Two genes (DYRK1A, DSCR1) in the putative critical region of chromosome 21 may be targets for therapy.

Developmental delay is universal (Tables 81-6 and 81-7; Fig. 81-10). Cognitive impairment does not uniformly affect all areas of development. Social development is relatively spared, but children with Down syndrome have considerable difficulty using expressive language. Understanding these individual developmental strengths will maximize the educational process for children with Down syndrome. Persons with Down syndrome often benefit from programs aimed at stimulation, development, and education. These programs are most effective in addressing social skills that often appear advanced for the intellectual delay. Children with Down syndrome also benefit from anticipatory guidance, which establishes the protocol for screening, evaluation, and care for patients with genetic syndromes and chronic disorders (Table 81-8). Up to 15% of children with Down syndrome have misalignment of cervical vertebra C1, which places them at risk for spinal cord injury with neck hyperextension or extreme flexion. Special Olympics recommends sports participation and training but requires x-ray examination (full extension and flexion views) of the neck prior to participation in sports that may result in hyperextension or radical flexion or pressure on the neck or upper spine; sports include diving starts in swimming, butterfly stroke, diving, pentathlon, high jump, equestrian sports, gymnastics, football, soccer, alpine skiing, and warm up exercises placing stress on the head and neck. If atlantoaxial instability is diagnosed, Special Olympics will permit participation if the parents or guardians request so and only after obtaining written certification from a physician and acknowledgment of the risks by the parent or guardian.

The majority of children with Down syndrome do not have behavior problems. It is estimated that psychiatric comorbidity is 18-38% in this population. These estimates are higher than in unaffected children, but they are lower than in children with similar levels of intellectual disability from other etiologies. All maladaptive behaviors in persons with Down syndrome are stereotype, but they are lower than in children with similar levels of intellectual delay. The life expectancy for children with Down syndrome is reduced and is approximately 50-55 yr. Little prospective information about the secondary medical problems of adults with Down syndrome is known. Retrospective studies have shown premature aging and an increased risk of Alzheimer disease in adults with Down syndrome. These studies have also shown unexpected negative associations between Down syndrome and other medical comorbidities. Persons with Down syndrome have fewer than expected deaths caused by solid tumors and ischemic heart disease. This same study reported increased risk of adult deaths due to congenital heart disease, seizures, and leukemia. In one large study, leukemias accounted for 60% of all cancers in people with Down syndrome.

*Hall’s criteria to aid in diagnosis.
syndrome and 97% of all cancers in children with Down syndrome. There was decreased risk of solid tumors in all age groups, including neuroblastomas and nephroblastomas in children with Down syndrome and epithelial tumors in adults with Down syndrome.

Most adults with Down syndrome are able to perform activities of daily living. However, most adults with Down syndrome have difficulty with complex financial, legal, or medical decisions. In most circumstances, a conservator is appointed for the adult with Down syndrome.

The risk of having a child with trisomy 21 is highest in women who conceive at >35 yr of age. Even though younger women have a lower risk, they represent half of all mothers with babies with Down syndrome because of their higher overall birth rate.

All women should be offered screening for Down syndrome in their 2nd trimester by means of 4 maternal serum tests (free β-human chorionic gonadotropin [β-hCG], unconjugated estriol, inhibin, and α-fetoprotein). This is
known as the quad screen; it can detect up to 80% of Down syndrome pregnancies compared to 70% in the triple screen. Both tests have a 5% false-positive rate. There is a method of screening during the 1st trimester using fetal nuchal translucency (NT) thickness that can be done alone or in conjunction with maternal serum β-hCG and pregnancy-associated plasma protein-A (PAPP-A). In the 1st trimester, NT alone can detect ≤70% of Down syndrome pregnancies, but with β-hCG and PAPP-A, the detection goes up to 87%. If both 1st and 2nd trimester screens are combined using NT and biochemical profiles (integrated screen), the detection rate goes up to 95%. If only 1st trimester quad screening is done, maternal serum α-fetoprotein (which is decreased in affected pregnancies) is recommended as a 2nd trimester follow-up.

Detection of cell free fetal DNA in maternal plasma is also diagnostic. The noninvasive detection of fetal trisomy 21 by analyzing cell-free fetal DNA in maternal serum is an important advance in prenatal diagnosis of Down syndrome. Next-generation DNA sequencing has reduced the cost of this procedure, which has a high degree of accuracy (98% detection rate) and applicability. The prenatal screens are also useful for other trisomies, although the detection rates may be different from those given for Down syndrome.

In approximately 95% of the cases of Down syndrome there are 3 copies of chromosome 21. The majority of translocations in Down syndrome are fusions at the centromere between chromosomes 13, 14, 15, 21, and 22 known as Robertsonian translocations. The translocations can be de novo or inherited. Very rarely is Down syndrome diagnosed in a patient with only a part of the long arm of chromosome 21 in triplicate (partial trisomy). Isochromosomes and ring chromosomes are other rarer causes of trisomy 21. Down syndrome patients without a visible chromosome abnormality are the least common. It is not possible to distinguish the phenotypes of persons with full trisomy 21 and those with a translocation. Representative genes on chromosome 21 and their potential effects on development are noted in Table 81-9. Patients who are mosaic tend to have a milder phenotype.

Chromosome analysis is indicated in every person suspected of having Down syndrome. If a translocation is identified, parental chromosome studies must be performed to determine whether one of the parents is a translocation carrier, which carries a high recurrence risk for having another affected child. That parent might also have other family members at risk. Translocation (21;21) carriers have a 100% recurrence risk for a chromosomally abnormal child, and other Robertsonian translocations, such as t(14;21), have a 5-7% recurrence risk when transmitted by females. Genomic dosage imbalance contributes through direct and indirect pathways to the Down syndrome phenotype and its phenotypic variation.

Tables 81-10 and 81-11 provide more information on other aneuploidies and partial autosomal aneuploidies (Figs. 81-11 to 81-14).

81.3 Abnormalities of Chromosome Structure

Carlos A. Bacino and Brendan Lee

TRANSLOCATIONS

Translocations, which involve the transfer of material from 1 chromosome to another, occur with a frequency of 1 in 500 liveborn human infants. They may be inherited from a carrier parent or appear de novo, with no other affected family member. Translocations are commonly reciprocal or Robertsonian, involving 2 chromosomes (Fig. 81-15).

Reciprocal translocations are the result of breaks in nonhomologous chromosomes, with reciprocal exchange of the broken segments. Carriers of a reciprocal translocation are usually phenotypically normal but are at an increased risk for miscarriage caused by transmission of unbalanced reciprocal translocations and for bearing chromosomally abnormal offspring. Unbalanced translocations are the result of abnormalities in the segregation or crossover of the translocation carrier chromosomes in the germ cells.

Robertsonian translocations involve 2 acrocentric chromosomes (chromosomes 13, 14, 21, and 22) that fuse near the centromeric region with a subsequent loss of the short arms. Because the short arms of all 5 pairs of acrocentric chromosomes have multiple copies of genes for ribosomal RNA, loss of the short arm of 2 acrocentric chromosomes has no deleterious effect. The resulting karyotype has only 45 chromosomes, including the translocated chromosome that is made up of the long arms of the 2 fused chromosomes. Carriers of Robertsonian translocations are usually phenotypically normal.

However, they are at increased risk for miscarriage and unbalanced translocations in phenotypically abnormal offspring.

In some rare instances, translocations can involve 3 or more chromosomes, as seen in complex rearrangements. Another, less common type is the insertional translocation. Insertional translocations result from a piece of chromosome material that breaks away and later is reinserted inside the same chromosome at a different site or inserted in another chromosome.

INVERSIONS

An inversion requires that a single chromosome break at 2 points; the broken piece is then inverted and joined into the same chromosome. Inversions occur in 1 in 100 live births. There are 2 types of inversions: pericentric and paracentric. In pericentric inversions, the breaks are in the 2 opposite arms of the chromosome and include the centromere. They are usually discovered because they change the position of the centromere. The breaks in paracentric inversions occur in only 1 arm. Carriers of inversions are usually phenotypically normal, but they are at increased risk for miscarriages, typically in paracentric inversions, and chromosomally abnormal offspring in pericentric inversions.

DELETIONS AND DUPLICATIONS

Deletions involve loss of chromosome material and, depending on their location, they can be classified as terminal (at the ends of chromosomes) or interstitial (within the arms of a chromosome). They may be isolated or they may occur along with a duplication of another chromosome segment. The latter typically occurs in unbalanced reciprocal chromosomal translocation secondary to abnormal crossover or segregation in a translocation or inversion carrier.

A carrier of a deletion is monosomic for the genetic information of the missing segment. Deletions are usually associated with intellectual disability and malformations. The most commonly observed deletions in routine chromosome preparations include 1p−, 4p−, 5p−, 9p−, 11p−, 13q−, 18p−, 18q−, and 21q− (Table 81-12 and Fig. 81-16), all distal or terminal deletions of the short or the long arms of chromosomes. Deletions may be observed in routine chromosome preparations, and deletions and translocations larger than 5-10 Mbp are usually visible microscopically.

High-resolution banding techniques, FISH, and molecular studies like aCGH can reveal deletions that are too small to be seen in ordinary or routine chromosome spreads (see Fig. 81-7). Microdeletions involve loss of small chromosome regions, the largest of which are detectable only with prophase chromosome studies and/or molecular methods. For submicroscopic deletions, the missing piece can only be detected using molecular methodologies such as DNA-based studies like aCGH or FISH. The presence of extra genetic material from the same chromosome is referred to as duplication. Duplications can also be sporadic or result from abnormal segregation in translocation or inversion carriers.

Microdeletions and microduplications usually involve regions that include several genes, so that the affected individuals can have a distinctive phenotype depending on the number of genes involved. When such a deletion involves more than a single gene, the condition is referred to as a contiguous gene deletion syndrome (Table 81-13). With the advent of clinically available aCGH, a large number of duplications, most of them microduplications, have been uncovered. Most of those microduplication syndromes are the reciprocal duplications of the known deletions or microdeletion counterparts and have distinctive clinical features (Table 81-14).

Subtelomeric regions are often involved in chromosome rearrangements that cannot be visualized using routine cytogenetics. Telomeres, which are the distal ends of the chromosomes, are gene-rich regions. The distal structure of the telomeres is essentially common to all chromosomes, but proximal to those, there are unique regions known as subtelomeres, which typically involved in deletions and most other chromosome rearrangements. Small subtelomeric deletions, duplications, or rearrangements (translocations, inversions) may be relatively common in nonspecific intellectual disability with minor anomalies. Subtelomeric rearrangements have been found in 3-7% of children.

Figure 81-15 A, Schematic diagram (left) and partial G-banded karyotype (right) of a reciprocal translocation between chromosome 2 (blue) and chromosome 8 (pink). The breakpoints are on the long (q) arm of both chromosomes at bands 2q33 and 8q24.1, with the reciprocal exchange of material between the derivative (der) chromosomes 2 and 8. This translocation is balanced, with no net gain or loss of material. The nomenclature for this exchange is t(2;8)(q33;q24.1). B, Schematic diagram (left) and partial G-banded karyotype (right) of a Robertsonian translocation between chromosomes 13 (blue) and 14 (pink). The breakpoints are at the centromere (band q10) of both chromosomes, with fusion of the long arms into a single derivative chromosome and loss of the short (p) arm material. The nomenclature for this exchange is der(13;14)(q10;q10).

</table>
with moderate to mild intellectual disability and 0.5% of children with mild intellectual disability.

Clinical features (>30%) include short stature, microcephaly, hypertelorism, nose and ear abnormalities, and cryptorchidism. This group is also characterized by a family history of intellectual disability and an increased likelihood of restricted growth beginning in the prenatal period. Telomere mutations have also been associated with dyskeratosis congenita and other aplastic anemia syndromes as well as pulmonary or hepatic fibrosis. Both the subtelomeric rearrangements and the microdeletion and microduplication syndromes are typically diagnosed by molecular techniques like aCGH, FISH, and multiple ligation-dependent primer amplification. Recent studies show that aCGH can detect 14-18% of abnormalities in patients who are previously known to have normal chromosome studies.

**INSERTIONS**

Insertions occur when a piece of a chromosome broken at 2 points is incorporated into a break in another part of a chromosome. A total of 3 breakpoints are then required, and they can occur between 2 or within 1 chromosome. A form of nonreciprocal translocation, insertions are rare. Insertion carriers are at risk of having offspring with deletions or duplications of the inserted segment.
ISOCHROMOSOMES

Isochromosomes consist of 2 copies of the same chromosome arm joined through a single centromere and forming mirror images of one another. The most commonly reported autosomal isochromosomes tend to involve chromosomes with small arms. Some of the more common chromosome arms involved in this formation include 5p, 8p, 9p, 12p, 18p, and 18q. There is also a common isochromosome abnormality seen in the long arm of the X chromosome, and associated with Turner syndrome. Individuals who have 1 isochromosome within 46 chromosomes are monosomic for genes in the lost short arm and trisomic for the genes present in the long arm of the X chromosome.

MARKER AND RING CHROMOSOMES

Marker chromosomes are rare and are usually chromosome fragments that are too small to be identified by conventional cytogenetics; they usually occur in addition to the normal 46 chromosomes. Most are sporadic (70%); mosaicism is often (50%) noted because of the mitotic instability of the marker chromosome. The incidence in newborn infants is 1 in 3,300, and the incidence in persons with intellectual disability is 1 in 300. The associated phenotype ranges from normal to severely abnormal depending on the amount of chromosome material and number of genes associated with the fragment.

Ring chromosomes, which are found for all human chromosomes, are rare. A ring chromosome is formed when both ends of a chromosome are deleted and the ends are then joined to form a ring. Depending on the amount of chromosome material that is lacking or in excess (if the ring is in addition to the normal chromosomes), a patient with a ring chromosome can appear normal or nearly normal or can have intellectual disability and multiple congenital anomalies.

Marker and ring chromosomes can be found in the cells of solid tumors of children the cells of whose organs do not contain this additional chromosomal material.

81.4 Sex Chromosome Aneuploidy
Carlos A. Bacino and Brendan Lee

About 1 in 400 males and 1 in 650 females have some form of sex chromosome abnormality. Considered together, sex chromosome abnormalities are the most common chromosome abnormalities seen in liveborn infants, children, and adults. Sex chromosome abnormalities can be either structural or numerical and can be present in all cells or in a mosaic form. Those affected with these abnormalities might have few or no physical or developmental problems (Table 81-15).

TURNER SYNDROME

Turner syndrome is a condition characterized by complete or partial monosomy of the X chromosome and defined by a combination of phenotypic features (Table 81-16). Half of the patients with Turner syndrome have a 45,X chromosome complement. The other half exhibits mosaicism and varied structural abnormalities of the X or Y chromosome. Maternal age is not a predisposing factor for children with 45,X. Turner syndrome occurs in approximately 1 in 5,000 female live births. In 75% of patients, the lost sex chromosome is of paternal origin (whether an X or a Y). 45,X is one of the chromosome abnormalities most often associated with spontaneous abortion. It has been estimated that 95-99% of 45,X conceptions are miscarried.

Clinical findings in the newborns can include small size for gestational age, webbing of the neck, protruding ears, and lymphedema of the hands and feet, although many newborns are phenotypically normal (Fig. 81-17). Older children and adults have short stature and exhibit variable dysmorphic features. Congenital heart defects (40%) and structural renal anomalies (60%) are common. The most common heart defects are bicuspid aortic valves, coarctation of the aorta, aortic stenosis, and mitral valve prolapse. The gonads are generally streaks of fibrous tissue (gonadal dysgenesis). There is primary amenorrhea and lack of secondary sex characters. These children should receive regular endocrinologic testing (see Chapter 586). Most patients tend to be of normal intelligence, but intellectual disability is seen in up to 6% of affected children. They are also at increased risk for behavioral problems and deficiencies in spatial and motor perception. Guidelines for health supervision for children with Turner syndrome are published by the American Academy of Pediatrics and include pubertal induction, as well as treatment with growth hormone and oxandrolone.

Patients with 45,X/46,XY mosaicism, can have Turner syndrome, although this form of mosaicism can also be associated with male pseudohermaphroditism, male or female genitalia in association with...

Table 81-16 Signs Associated with Turner Syndrome

- Short stature
- Congenital lymphedema
- Horseshoe kidneys
- Patella dislocation
- Increased carrying angle of elbow (cubitus valgus)
- Madelung deformity (chondrodysplasia of distal radial epiphysis)
- Congenital hip dislocation
- Scoliosis
- Widespread nipples
- Shield chest
- Redundant nuchal skin (in utero cystic hygroma)
- Low posterior hairline
- Coarctation of aorta
- Bicuspid aortic valve
- Cardiac conduction abnormalities
- Hypoplastic left-heart syndrome and other left-heart abnormalities
- Gonadal dysgenesis (infertility, primary amenorrhea)
- Gonadoblastoma (increased risk if Y chromosome material is present)
- Learning disabilities (nonverbal perceptual motor and visuospatial skills) (in 70%)
- Developmental delay (in 10%)
- Social awkwardness
- Hypothyroidism (acquired in 15-30%)
- Type 2 diabetes mellitus (insulin resistance)
- Strabismus
- Cataracts
- Red-green color blindness (as in males)
- Recurrent otitis media
- Sensorineural hearing loss
- Inflammatory bowel disease
- Celiac disease (increased incidence)

Figure 81-17 Redundant nuchal skin (A) and puffiness of the hands (B) and feet (C) in Turner syndrome. (From Sybert VP, McCauley E: Turner’s syndrome, N Engl J Med 351:1227–1238, 2004. Copyright © 2004 Massachusetts Medical Society.)
mixed gonadal dysgenesis, or a normal male phenotype. This variant is estimated to represent approximately 6% of patients with mosaic Turner syndrome. Some of the patients with Turner syndrome phenotype and a Y cell line exhibit masculinization. Phenotypic females with 45,X/46,XY mosaicism have a 15-30% risk of developing gonadal dysgenesis. The risk for the patients with a male phenotype and external testes is not so high, but tumor surveillance is nevertheless recommended. The American Academy of Pediatrics has recommended the use of FISH analysis to look for Y-chromosome mosaicism in all 45,X patients. If Y chromosome material is identified, laparoscopic gonadectomy is recommended.

Noonan syndrome shares many clinical features with Turner syndrome (old name was pseudo-Turner syndrome), although it is an autosomal dominant disorder resulting from mutations in several genes that are involved in the RAS-MAPK (mitogen-activated protein kinase) pathway. The most common of these is PTEN (50%), which encodes a protein-tyrosine phosphatase (SHIP-2) on chromosome 12q24.1. Other genes include SOS1 in 10-13%, RAF1 in 3-17%, KRAS <5%, BRAF <2%, and MAP2K <2%. Overlapping phenotypes are seen in LEOPARD (lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness) syndrome, cardiofaciocutaneous syndrome, and Costello syndrome; these are Noonan-related disorders. Features common to Noonan syndrome include short stature, low posterior hairline, shield chest, congenital heart disease, and a short or webbed neck (Table 81-17). In contrast to Turner syndrome, Noonan syndrome affects both sexes and has a different pattern of congenital heart disease, typically involving right-sided lesions.

**KLINEFELTER SYNDROME**

Persons with Klinefelter syndrome are phenotypically male; this syndrome is the most common cause of hypogonadism and infertility in males and the most common sex chromosome aneuploidy in humans (see Chapter 583). Eighty percent of children with Klinefelter syndrome have a male karyotype with an extra chromosome X-47,XXX; the remaining 20% have multiple sex chromosome aneuploidies (48,XXXY; 48,XXYY; 49,XXXXY), mosaicism (46,XY/47,XXX), or structurally abnormal X chromosomes. The greater the aneuploidy, the more severe the mental impairment and dysmorphism. Early studies showed that the birth prevalence is approximately 1 in 1,000 males. The current prevalence of 47,XXX appears to have increased to approximately 1 in 580 liveborn boys; the reasons for this are still unknown. Errors in paternal nondisjunction in meiosis I account for half of the cases.

Puberty occurs at the normal age, but the testes remain small. Patients develop secondary sex characters late; 50% develop gynecomastia. They have taller stature. Because many patients with Klinefelter syndrome are phenotypically normal until puberty, the syndrome often goes undiagnosed until they reach adulthood, when their infertility aids in their clinical identification. Patients with 46,XY/47,XXX have a better prognosis for testicular function. Their intelligence shows variability and ranges from above to below average. Persons with Klinefelter syndrome can show behavioral problems, learning disabilities, and deficits in language. Problems with self-esteem are often the case with adolescents and adults. Substance abuse, depression, and anxiety have been reported in adolescents with Klinefelter syndrome. Those who have higher X chromosome counts show impaired cognition. It has been estimated that each additional X chromosome reduces the IQ by 10-15 points, when comparing these persons with their normal siblings. The main effect is seen in language skills and social domains.

**47,XXY**

The incidence of 47,XXY is approximately 1 in 800-1,000 males, with many cases remaining undiagnosed, because most affected individuals have a normal appearance and normal fertility. The extra Y is the result of nondisjunction at paternal meiosis II. Those with this abnormality have normal intelligence but are at risk for learning disabilities. Behavioral abnormalities including hyperactive behavior, pervasive developmental disorder, and aggressive behavior have been reported. Early reports that assigned stigmata of criminality to this disorder have long been disproved.

### 81.5 Fragile Chromosome Sites

Carlos A. Bacino and Brendan Lee

Fragile sites are regions of chromosomes that show a tendency for separation, breakage, or attenuation under particular growth conditions. They appear as a gap in the staining. At least 120 chromosomal loci, many of them heritable, have been identified as fragile sites in the human genome (see Table 80-2).

One fragile site that has clinical significance is the one on the distal long arm of chromosome Xq27.3 associated with the fragile X syndrome. Fragile X accounts for 3% of males with intellectual disability. There is another fragile site on the X chromosome (FRAXE on Xq28) that has also been implicated in mild intellectual disability. The FRA11B (11q23.3) breakpoints are associated with Jacobsen syndrome (condition caused by deletion of the distal long arm of chromosome 11). Fragile sites can also play a role in tumorigenesis. CGG repeat expansion silences the gene producing fragile X mental retardation protein (FMRP) that regulates the translation of multiple mRNAs to specific proteins, thus affecting synaptic function. FMRP deficiency upregulates the metabotropic glutamate receptor (mGluR5) pathway. FMRP deficiency also alters the expression of matrix metalloproteinase (MMP) 9.

The main clinical manifestations of fragile X syndrome in affected males are intellectual disability, autistic behavior, macroorchidism, hyperextensible finger joints, and characteristic facial features (Table 81-18). Macroorchidism may not be evident until puberty. The facial features, which include a long face, large ears, and a prominent square jaw, become more obvious with age. Females affected with...
Bibliography

fragile X show varying degrees of intellectual disability and/or learning disabilities. Diagnosis of fragile X is possible by DNA testing that shows an expansion of a triplet DNA repeat inside the FMR1 gene on the X chromosome larger than 200 repeats. The expansion involves an area of the gene that contains a variable number of trinucleotide (CGG) repeats. The larger the triplet repeat expansion, the more significant the intellectual disability. In cases where the expansion is large, females can also manifest different degrees of intellectual disability. Males with premutation triple repeat expansions (50-200 repeats), have been found to have an adult, late onset progressive neurodegenerative disorder known as fragile X-associated tremor/ataxia syndrome.

Therapy of the diverse neuropsychiatric manifestations associated with fragile X syndrome is noted in Table 81-19. Inhibitors of the mGluR (overexpressed in fragile X) are undergoing clinical trials. In preliminary trials, minocycline (lowers MMP9) has resulted in short term improvements in anxiety, mood, and the clinical Global Impression Scale.

Bibliography is available at Expert Consult.

### 81.6 Mosaicism
Carlos A. Bacino and Brendan Lee

Mosaicism describes an individual or tissue that contains ≥2 different cell lines typically derived from a single zygote and the result of mitotic nondisjunction (see Fig. 81-1). Study of placental tissue from chorionic
Bibliography

Uniparental disomy (UPD) occurs when both chromosomes of a pair or areas from 1 chromosome in any individual have been inherited from a single parent. UPD can be of 2 types: uniparental isodisomy or uniparental heterodisomy. **Uniparental isodisomy** means that both chromosomes or chromosomal regions are identical (typically the result of monosomy rescue by duplication). **Uniparental heterodisomy** means that the 2 chromosomes are different members of a pair, both of which were still inherited from 1 parent. This results from a trisomy that is later reduced to disomy, leaving 2 copies from 1 parent. The phenotypical result of UPD varies according to the chromosome involved, the parent who contributed the chromosomes, and whether it is isodisomy or heterodisomy. Three types of phenotypic effects are seen in UPD: those related to imprinted genes (i.e., the absence of a gene that is normally expressed only when inherited from a parent of a specific sex), those related to the uncovering of autosomal recessive disorders, and those related to a vestigial aneuploidy producing mosaicism (see Chapter 80).

In uniparental isodisomy, both chromosomes or regions (and thus the genes) in the pair are identical. This is particularly important when the parent is a carrier of an autosomal recessive disorder. If the offspring of a carrier parent has UPD with isodisomy for a chromosome that carries an abnormal gene, the abnormal gene will be present in 2 copies and the phenotype will be that of the autosomal recessive disorder; the child has an autosomal recessive disorder even though only 1 parent is a carrier of that recessive disorder. It is estimated that all human beings carry approximately 20 abnormal autosomal recessive genes. Some autosomal recessive disorders like spinal muscular atrophy, cystic fibrosis, cartilage-hair hypoplasia, α and β-thalassemias, and Bloom syndrome have been reported in cases of UPD. The possibility of uniparental isodisomy should also be considered when a person is affected with >1 recessive disorder because the abnormal genes for both disorders could be carried on the same isodisomic chromosome. Uniparental isodisomy is a rare cause of recessively inherited disorders. Uniparental isodisomies can also be detected by SNP microarrays.

**Maternal UPD** involving chromosomes 2, 7, 14, and 15 and **paternal UPD** involving chromosomes 6, 11, 15, and 20 are associated with phenotypic abnormalities of growth and behavior. UPD of maternal chromosome 7 is associated with a phenotype similar to Russell-Silver syndrome with intrauterine growth restriction. These phenotypic effects may be related to imprinting (see under Imprinting, below) (Fig. 81-18).

UPD for chromosome 15 is seen in some cases of Prader-Willi syndrome and Angelman syndrome. In **Prader-Willi syndrome**, approximately 25-29% of cases have maternal UPD (missing the paternal chromosome 15). In **AngeImman syndrome**, paternal UPD of chromosome 15 is rarer and is observed in approximately 5% of the cases (missing the maternal chromosome 15). The phenotype for Prader-Willi syndrome (Fig. 81-19) and Angelman syndrome in cases of UPD is thought to result from the lack of the functional contribution from a particular parent of chromosome 15. In Prader-Willi syndrome the paternal contribution is missing, and the maternal contribution is missing in Angelman syndrome. Prader-Willi may be due to paternal deficiency of HB11-85 snoRNAs (small nucleolar RNAs). These findings suggest that there are differences in function of certain regions of chromosome 15, depending on whether it is inherited from the mother or from the father.

UPD most commonly arises when a pregnancy starts off as a **trisomic conception followed by trisomy rescue**. Because most trisomies are lethal, the fetus can only survive if a cell line loses 1 of the extra chromosomes to revert to the disomic state. One-third of the time, the disomic cell line is uniparental. This is the typical mechanism for Prader-Willi syndrome, and it is often associated with advanced maternal age. The embryo starts off as trisomy 15 secondary to maternal meiosis I nondisjunction, followed by random loss of the paternal chromosome. In this case, the disomic cell line becomes the more viable one and outgrows the trisomic cell line. When mosaic trisomy is found at prenatal diagnosis, care should be taken to determine whether UPD has resulted and whether the chromosome involved is one of the disomies known to be associated with phenotypic abnormalities. There must always be concern that some residual cells that are trisomic are present in some tissues, leading to malformations or

---

**81.7 Chromosome Instability Syndromes**

Carlos A. Bacino and Brendan Lee

Chromosome instability syndromes, formerly known as chromosome breakage syndromes, are characterized by an increased risk of malignancy and specific phenotypes. They display autosomal recessive inheritance and have an increased frequency of chromosome breakage and/or rearrangement, either spontaneous or induced. They result from specific defects in DNA repair, cell cycle control, and apoptosis. The resulting chromosomal instability leads to the increased risk of developing neoplasms. The classic chromosome instability syndromes are Fanconi anemia, ataxia telangiectasia, Nijmegen syndrome, ICF (immunodeficiency, centromere instability, and facial anomalies) syndrome, Roberts syndrome, Werner syndrome, and Bloom syndrome.

**81.8 Uniparental Disomy and Imprinting**

Carlos A. Bacino and Brendan Lee

**Uniparental disomy** (UPD) occurs when both chromosomes of a pair or areas from 1 chromosome in any individual have been inherited from a single parent. UPD can be of 2 types: uniparental isodisomy or
dysfunction. The presence of aggregates of trisomic cells might account for the spectrum of abnormalities seen in persons with UPD.

**IMPRINTING**

Traditional genetics has for many years suggested that most genes are equally expressed when inherited from maternal versus paternal lineages. The only exception to this rule were genes on the X chromosome that are subject to inactivation, and the immunoglobulin genes subject to allelic exclusion, a phenomenon that results in monoallelic expression of a particular immunoglobulin chain by switching on and off expression of parental alleles. Genomic imprinting occurs when the phenotypic expression of a gene depends on the parent of origin for certain genes or in some cases entire chromosome regions. Whether the genetic material is expressed or not depends on the sex of the parent from whom it was derived. Genomic imprinting can be suspected in some cases on the basis of a pedigree. In these pedigrees, the disease is always transmitted from 1 sex and could be passed on silently to the opposite sex (Figs. 81-20 and 81-21).

Imprinting probably occurs in many different parts of the human genome and is thought to be particularly important in gene expression related to development, growth, cancer, and even behavior; over 60 genes have been classified as imprintable. Imprinting disorders may arise from UPD, deletions or duplications, epigenetic aberrant methylation patterns, or point mutations in a specific gene.

A classic example of imprinting disorder is seen in Prader-Willi syndrome and Angelman syndrome, 2 very different clinical conditions. These syndromes are usually associated with deletion of the same region in the proximal long arm of chromosome 15. A deletion on the paternally derived chromosome causes Prader-Willi syndrome, in which the maternally derived copy is still intact but some of the imprinted genes within this region normally remain silent. In contrast, a maternal deletion of the same region causes Angelman syndrome, leaving intact the paternal copy that in this case has genes that are also normally silent. In other situations, UPD can lead to the same diagnosis. Maternal UPD for chromosome 15 results in Prader-Willi syndrome due to lack of the paternal chromosome 15 contribution. In contrast, in Angelman syndrome, the UPD is always paternal, with no maternal contribution (Table 81-20). Many other disorders are associated with this type of parent of origin effect, as in some cases of Beckwith-Wiedemann syndrome, Russell-Silver syndrome, and neonatal diabetes.

D, External genitalia after laparoscopic orchiopexy at 13 mo. Parental informed consent, as approved by the Baylor College of Medicine Institutional Review Board, was obtained to publish the photographs. (From Sahoo T, del Gaudio D, German JR, et al: Prader-Willi phenotype caused by paternal deficiency for the HBII-85 C/D box small nucleolar RNA cluster, Nat Genet 40:719–721, 2008.)

Figure 81-20 In this hypothetical pedigree suggestive of imprinting, phenotypic effects occur only when the mutated gene is transmitted from the mother, but not when it is transmitted from the father, that is, maternal deficiency. Equal numbers of males and females can be affected and not affected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; that is, in maternal deficiency disorders (also termed paternal imprinting), there are "skipped" nonmanifesting females. This is theoretical, because in most clinical scenarios of maternal deficiency, such as Angelman syndrome, affected persons do not reproduce.
In theoretical pedigrees suggestive of paternal deficiency (maternal imprinting), phenotypic effects occur only when the mutated gene is transmitted from the father, but not when transmitted from the mother. Equal numbers of males and females can be affected and not affected phenotypically in each generation. In a theoretical situation, a nonmanifesting transmitter gives a clue to the sex of the parent who passes on the expressed genetic information; that is, in paternal deficiency (also known as maternal imprinting), there are “skipped” nonmanifesting males. In real-life clinical instances of Prader-Willi syndrome, affected persons do not reproduce.
Genetic studies are useful in diagnosing and treating rare pediatric conditions, often alleviating suffering, extending life, and, in the case of neonatal metabolic and presymptomatic screening, preventing injury before symptoms develop. Genetic studies can also contribute to the understanding of more common diseases, such as asthma and diabetes. An understanding of the complex and potentially multiple pathways leading to disease is crucial for the development of new therapies and prevention strategies.

Common pediatric diseases are often multifactorial, and the combination of many genes and environmental factors triggers a complex sequence of events leading to disease. Each individual has variations in his or her set of genes; the cumulative effect of the individual's gene variants with each other and with the environment influence susceptibility to disease, response to various medications, and susceptibility to specific drug toxicities. The complexity of the combination of contributing factors increases the challenge of finding genetic variants that cause disease. Genetic tools include the completed human genome sequence, public databases of genetic variants, and the human haplotype map. In addition to public genetic databases, dramatic reduction in the cost of genotyping and DNA sequencing has allowed very large numbers of genetic variants to be efficiently tested in large numbers of patients. Most of these studies focus on common variants (those with frequencies >5%). New technologies for DNA sequencing are already allowing whole exome sequencing in many individuals at very low cost. This technology is being used to investigate the role of rare coding sequence variants in common diseases. The incorporation of these tools into large, well-designed population studies is the field of genetic epidemiology. Many new methods for analyzing genetic data have been developed, stimulating a renaissance in applied population genetics. So far, these methods of investigation have been used less extensively in pediatric diseases than in adult-onset conditions. This is a consequence of the relative lack of large-scale DNA sample sets for many common diseases of children.

We can now project that in the near future it will become routine to carry out “genomic profiling” by one technique or another for individual children. These methods will find clinical utility in decision algorithms for disease screening and initiation of treatment, drug selection, and targeted preventive strategies. The results will be of an unprecedented complexity, so that physicians and parents will increasingly rely on the coupling of genetic data to clinical decision support tools linked to the electronic health record.

82.1 Major Genetic Approaches to the Study of Common Pediatric Disorders

John W. Belmont and Brendan Lee

Figure 82-1 shows a model for the genetic contribution to health. Genetic variation that can have an impact on disease susceptibility is present in every person. Sometimes single-gene mutations cause a condition, as is the case for cystic fibrosis or sickle cell anemia. But other kinds of genetic variations can contribute much less strongly to the emergence of specific medical conditions, and the effect can depend upon exposure to certain environmental factors. One goal in medical genetics is to identify genes that contribute to disease in the hope of preventing the occurrence of disease, either by avoiding inciting environmental factors or by instituting interventions that reduce risk. For persons who cross the threshold of disease, the goal is to better understand the pathogenesis in the hope that this will suggest better approaches to treatment. Common genetic variation can also influence response to medications and the risk of toxicities of various medications and environmental toxins.
Complex traits may be inherently difficult to study if there are problems with the precision of clinical diagnosis. This is particularly true of neurobehavioral traits. A starting point in the genetic analysis of a complex trait is to obtain evidence in support of a genetic contribution and to estimate the relative strength of genetic and environmental factors. Complex traits typically exhibit familial clustering, but are not transmitted in a regular pattern like autosomal dominant or recessive inheritance. Complex traits often show variation among different ethnic or racial groups, possibly reflecting the differences in gene variants among these groups.

Assessing the potential genetic contribution begins by determining whether the trait is seen among related individuals more often than in the general population. A common measure of familiality is the first-degree relative risk (usually designated by the symbol λr), which is equal to the ratio of the prevalence rate in siblings and/or parents to the prevalence rate in the general population. For example, the λr for type 1 diabetes is about 15. The relative strength of genetic and non-genetic risk factors can be estimated by variance components analysis, and the heritability of a trait is the estimate of the fraction of the total variance contributed by genetic factors (Fig. 82-2).

It is not uncommon for a minority of cases of common diseases like diabetes to be caused by single-gene mutations (mendelian inheritance), chromosomal disorders, and other genomic disorders. These less-common causes of the disease can often provide important insight into the most important molecular pathways involved. Chromosomal regions with genes that might contribute to disease susceptibility could theoretically be located with linkage mapping, which locates regions of DNA that are inherited in families with the specific disease. But practically, this has turned out to be quite difficult for most complex traits either because of a dearth of families or because the effect of individual genetic loci is weak.

Genetic association studies are more powerful in identifying common gene variants (>5% in the population) that confer increased risk of disease, but they fail if the disease-causing gene variants are relatively rare. Detection of the modest effect of each variant and interactions with environmental factors requires well-powered studies that often include thousands of subjects. A number of parallel approaches for analyzing the aggregate effects of rare variants in genes have also been developed. Such rare variant association methods also seem to require large sample sizes because the gene effects have also proven to be relatively weak.

Linkage mapping and association studies require markers along the DNA that can be ascertained, or genotyped, with large-scale, high-throughput laboratory techniques. Markers that are typically used are in the forms of microsatellites and single-nucleotide polymorphisms (SNPs; Fig. 82-3). Although humans all have the same genetic material, each person's genome is slightly different. A sample of the same region of genome from 50 people will reveal that approximately 1 in every 200 bases varies from the more common form. Although most SNPs lack any obvious function, a few alter the amino acid sequence of the protein or affect regulation of gene expression. Some of these functional alterations directly affect susceptibility to disease. A complex clinical phenotype can be defined by the presence or absence of a disease as a dichotomous trait, or by selection of a clinically meaningful variable such as serum glucose in type 2 diabetes, which is a continuous or quantitative trait.

Although it might not be possible to define subgroups of patients in advance based on common disease mechanisms, the more uniform the phenotype, the more likely that a genetic study will be successful. Locus heterogeneity refers to the situation in which a trait results from the independent action of more than 1 gene. Allelic heterogeneity indicates that more than 1 variant in a particular gene can contribute to disease risk. The development of a trait or disease from a nongenetic mechanism results in a phenocopy. These 3 factors often contribute to the difficulty in identifying individual disease susceptibility genes because they reduce the effective size of the study population.

A person bearing any variant or allele (inherited unit, DNA segment, or chromosome) in a gene has a certain probability of being affected with a specific gene variant-associated disease. This is called the

![Figure 82-2 Heritability concept. The phenotypic variance of a particular trait can be partitioned between the contributions of the genetic variance, the environmental variance, and the measurement variance. This is usually empirically determined. Heritability is defined by the proportion of the phenotypic variance that is accounted for by the genetic variance. One can estimate the heritability from correlation of a quantitative trait between relatives.](image1)

![Figure 82-3 Different combinations of SNPs are found in different individuals. The locations of these SNPs can be pinpointed on maps of human genes. Subsequently, they can be used to create profiles that are associated with difference in response to a drug, such as efficacy and nonefficacy.](image2)
penetrance. Some diseases manifest signs only later in life (age-related penetrance), which could lead to misclassifying children who actually have the disease-producing gene as unaffected. Single-gene disorders are typically caused by mutations with relatively high penetrance, but some common variants have very low penetrance because their overall contribution to the disease is small. Many such common variants can contribute to disease risk for a complex trait. For example, normal human height is influenced by more than 400 genes.

Ideally, important environmental exposures should be measured and accounted for in a population because there may be a dependent interaction between the environmental factor and specific genetic variant. An example is the likely requirement for a viral infection preceding onset of type 1 diabetes. Although gene X environment interactions are strongly suspected to play an important role in common diseases, it is difficult to identify and measure them. Very large studies with uniform collection of information about environmental exposures are rare. New methods, such as genome-wide analysis of DNA methylation, may show evidence of environmental effects—so-called developmental programming. This information might be used to discover and validate gene-environment interactions.

LINKAGE MAPPING
Linkage studies were used in the past to isolate genes that cause rare genetic syndromes; modified methods have been used to identify chromosomal regions linked to more common diseases. Linkage studies involve tagging segments of a person's genome with markers that allow identification of segments that have been inherited through the family along with disease. The markers are typically microsatellites or SNPs that define and help to distinguish which type of an allele any person carries. The type of an allele is referred to as a genotype. Linkage analyses of common diseases have shown inconsistent results. Factors such as heterogeneity, pleiotropy, variable expressivity, and reduced penetrance, in addition to variability in environmental exposures, weaken the power of linkage studies in complex traits.

GENETIC ASSOCIATION
For multifactorial common diseases, association analyses may be used to identify causally important genes. There are two types of association study: direct association, in which the causal variant itself is tested to see whether its presence correlates with disease, and indirect association, in which markers that are physically close to the biologically important variant are used as proxies. The correlation of markers with other genetic variants in a small region of the genome is called linkage disequilibrium. Indirect association is enabled by the construction of a detailed genetic map in 3 reference populations (Europeans, Asians, West Africans) through the International HapMap Project. SNPs that tag most of the genome have been identified and can be genotyped at low cost using specially designed microarrays.

Three basic study designs are used for association testing: a case-control design, in which the frequency of an allele in the affected group is compared with the unaffected group; a family-based control design, in which parents or siblings of an affected individual are used as the controls; and a cohort design, in which large numbers of subjects are ascertained and then followed for the onset of any number of diseases. The cohort analysis is very expensive and there are few true cohort studies.

Family-based control study designs are somewhat attractive for pediatric diseases because it is usually possible to enroll parents. These studies solve a major problem in testing for association because the parents are perfectly matched for genetic background. When parents are collected, the statistical test used for these studies is called the transmission disequilibrium test (TDT). TDT compares the transmitted genotype with the inferred nontransmitted genotype. The success of all association analysis depends on the design of a well-powered study, with enough subjects, and an accurately measured trait to avoid phenotypical misclassification. In large, population-based studies, confounding by ethnicity or population stratification could distort results. Some genetic variants are more common in people from a particular ethnic group, which could cause an apparent association of a variant with a disease, when the disease rate happens to be higher in that group. This association would not be a true association between an allele and a disease, because the association would be confounded by genetic background. The family-based tests using the TDT are immune to population stratification. However, TDT and related study designs are inherently less efficient than case-control studies. Newer methods for measuring subtle mismatching between cases and controls using many thousands of markers routinely genotyped in genome-wide association studies allow this effect to be accounted for.

Association studies should be a powerful tool to find genetic variation that confers risk to an individual; the effect of any one genetic variant will be a very small contribution to the complex disease pathway. Genetic variants have been found that implicate a novel gene in a process, motivating more in-depth research into systems that will affect disease outcome. Associations such as the ApoE4 variant with an increased risk of Alzheimer disease are noted by many studies. Many published association results are not reproducible; insufficient power and stratification might account for the inconsistencies. As of early 2014, more than 6000 disease associations for more than 600 medically important traits have been discovered and replicated in large studies.

New low-cost methods for sequencing the complete exomes and genomes of individuals will soon allow a more comprehensive evaluation of the full range of genetic variants involved in common diseases. The goal of the $1000 genome once seemed distant but may be achieved very soon. Rare genetic variants, including small insertions or deletions, could turn out to be extremely important in explaining the impact of genetic factors in important pediatric diseases such as autism, cardiovascular malformations, and other birth defects. Common traits such as obesity, diabetes, and autoimmune diseases might also be affected by rare variants. In common severe disorders like intellectual disability and complex heart malformations, de novo mutations (i.e., mutations not present in either parent) are likely to play an important role.

Chapter 83
Genetic Approaches to Rare and Undiagnosed Diseases
William A. Gahl, David R. Adams, Thomas C. Markello, Neal F. Boerkoel, and Cynthia J. Tifft

Rare and novel disorders often present in childhood and represent a diagnostic challenge that can be addressed using advanced genetic techniques.

SCOPE OF GENETIC DISEASE
An estimated 7000 rare disorders are recognized, and the existence of approximately 23,000 human genes suggests that many more genetic diseases will be discovered in the future. These genetic diseases comprise a set of maladies amenable to a variety of diagnostic approaches. Knowledge about the human genome creates a new opportunity to diagnose extremely rare disorders and discover new diseases. One
approach was taken by the National Institutes of Health (NIH) Undiagnosed Diseases Program (UDP).

Potential reasons patients may remain undiagnosed despite intensive prior investigation include:
- The genetic mutation had not previously been associated with the disease phenotype
- There is allelic heterogeneity (same gene but different mutation producing a different phenotype)
- There is locus heterogeneity (different genes producing similar phenotype)
- Presentation of monosymptomology or unusual features of a polysymptomatic or rare disease

The 3,000 patient applications to the UDP have involved collaboration between the referring healthcare team and the NIH group. Prior investigations are recounted in a summary letter from the referring clinician and documented with medical records that include photos, videos, imaging and histologic slides of biopsy material. Specialty consultants review the records and the UDP directors determine the next steps. The patients who are accepted come to the Clinical Center for a week-long inpatient admission. Approximately half of the patients with undiagnosed diseases have neurological disease; cardiovascular, rheumatology, immunology, and pulmonary problems are also frequent. Approximately 40% of accepted patients are children, among whom unknown multiple congenital anomalies and neurologic disorders are common.

**CLINICAL EVALUATION**

The term undiagnosed refers to patients who remain without a definitive diagnosis after an extensive workup. This occurs in part because every individual has a unique genetic and environmental background, and diseases express themselves in an unlimited number of ways. Undiagnosed conditions include those that have never been seen by the diagnostician, unusual presentations of otherwise recognizable conditions, and combinations of conditions that obfuscate each other’s identities. A thorough clinical investigation allows the clinician to broaden the differential diagnosis through research, consultation, clinical testing and consideration of atypical presentations of previously known diseases. Extensive phenotyping, imaging, and other tests provide better documentation of the presentation and make the case available for association with future newly discovered diseases, genetic variants, and patient cohorts.

A complete history anchors the data, and includes prenatal and neonatal findings, developmental milestones, growth pattern, onset and progression of symptoms and signs, precipitating influences, response to medications, and a pedigree to determine which family members are affected. Pertinent physical findings include dysmorphism, organomegaly, neurologic impairment, bone involvement, and dermatologic findings. Because many rare and novel disorders are multisystemic, consultants play a critical role in every diagnostic evaluation. Typical studies performed to address possible diagnoses are listed in Table 83-1. The evaluation of a pediatric neurology case involves even more extensive studies (Table 83-2).

An inpatient admission allows for close interaction among experts in different fields, informs the workup of complex cases, and often leads to a focus on the discovery of a new disease. In that situation, other family members need to be evaluated to definitively ascertain whether they are affected with the disorder under consideration.

**AVAILABLE COMMERCIAL LABORATORY GENETIC STUDIES**

Once phenotyping is complete, a differential list of genetic disorders can be compiled. Laboratory molecular testing is available for an increasingly large spectrum of molecular disorders. In many cases, several related diseases are included in a panel of molecular tests. Examples include X-linked cognitive impairment, hereditary spastic paraplegia, spastic paraplegia and gait, spinocerebellar ataxias, dystonias, and mitochondrial disorders. Some of these individual tests and panels are expensive, and added together they may exceed the cost of exome sequencing.

**SINGLE-NUCLEOTIDE POLYMORPHISM ARRAYS**

There are 2 technologies that are cost-effective for medical uses and can examine the entire genome with resolution at the level of a single base pair. These are single-nucleotide polymorphism (SNP) arrays (microarrays or chips) and next-generation sequencing. The human genome’s 3.2 billion bases include many that are polymorphic. Polymorphisms are bases that are not the usual one at a defined position and yet occur with a frequency of >1% within a given population. For any 2 individuals who are not closely related, there are approximately 2.5 × 10^6 SNPs that vary between them (and between each individual and the canonical human reference), or about 1 polymorphism for every 1,000 bases in the genome on average. Within a single ethnic population there is about 1 common SNP per 3,000-7,000 bases, where common means a greater than 10% chance that any 1 patient will be polymorphic (heterozygous) at that position. A few hundred thousand to a few million of these common SNPs can be included on a DNA hybridization array and examined simultaneously in a single laboratory test. This technique produces genome-wide results that reveal copy number variations; mosaicism is also revealed, as are regions of...
identity by descent. These results are very useful in complementing the next-generation sequencing results. One example of this is the use of the SNP deletion regions to denote where to look for a point mutation in the next-generation sequence of the child (to detect the compound heterozygous recessive pairing of a deletion with a point mutation).

**EXOME SEQUENCING**

Technical advances have allowed for massive DNA sequencing at a reasonable price, making it feasible to determine the sequence of the coding regions of almost all of the human genes. Because this involves 1.7% of the 3.2 billion bases in the human genome, **exome sequences** comprise approximately 60,000,000 bases. These satisfactorily cover 80–85% of the known genes, and are determined by sequencing short “reads” (DNA fragments) and aligning them to a composite reference sequence of the human genome. In part because of SNP interference with hybridization, ambiguities in alignment, and chemistry error rates, the average exome has about 20,000 bases (0.03%) that differ from the “reference” sequence and from any other single, unrelated human sequence of the same ethnic group. Most of these variants are inconsequential polymorphisms. The problem is that each of the 20,000 variants of unknown significance is a potential disease-causing variant, yet only 1 is the disease-causing mutation for a monogenic disorder (with perhaps 2 or 3 additional loci modifying severity). The task of the clinician is to reduce the credible variants from 20,000 to a manageable number, such as 5.

This process involves using “filters,” or programs that eliminate false-positive variants without eliminating the true variants. The single best filter uses the exome sequencing (ES) of nuclear family members (i.e., parents and siblings), but only if their true affected or unaffected status is certain. If, for example, an unaffected sibling’s gene has 2 variants on opposite alleles that are the same as those of the affected proband, then those variants can be eliminated as causing the proband’s disease. This emphasizes the importance of collecting family DNA and obtaining a very careful evaluation of family members. In general, having the proband, both parents and siblings provides sufficient power to reduce the candidate variants to a reasonable number for all mendelian inheritance models, assuming complete penetrance.

As an example, if autosomal recessive inheritance is postulated, then the ES analysis should require mutations on both alleles of the proband, with 1 of the 2 mutations present in 1 parent and the other
mutation present in the other parent. Affected sibs must have both mutations, and unaffected sibs must have either 1 or none. Software programs have succeeded using a homozygous recessive model, and for significantly deleterious variants, using a compound heterozygous recessive model.

Base changes that result in amino acid changes (missense mutations) are evaluated by programs that gauge the pathogenicity of the change. This involves estimates of how tightly the base is conserved over evolution, whether the amino acid change charge, size, or conformation, and, sometimes, where in the protein the amino acid change resides. Analyzing how changes in the gene's code influence protein function remains an inexact science, but approximations have been used with some success. Software programs, including PolyPhen-2, SIFT, and MutationTaster, rate the pathogenicity of amino acid changes. In addition, evolutionary consistency of a base can be evidence of deleteriousness of a change in that base, even if it is not involved in an amino acid change (promoter binding domains, methylation sites). Finally, some filters compare variants to databases that list changes considered to be benign (database of single-nucleotide polymorphisms), known to cause diseases other than those under investigation, or simply found frequently in many random genomes (1000 Genomes). These databases can be very helpful, but they are not entirely reliable because their entries have not been curated in all cases to a medically useful level of confidence.

The analysis of exome sequences is advancing rapidly, based upon the development of new filters and larger, better, and more informative databases. However, several key points need to be considered when employing genome-scale sequencing for clinical diagnostics.

Positive predictive value gives the likelihood that a positive test is a true positive. This is higher in a population in which a disease is frequent and lower in a population where the disease is rare. A person being tested with ES will show no clinical signs or symptoms of most of the genetic diseases for which the ES tests. Therefore, many apparently positive findings will be false positives. This manifests as the frequent occurrence of DNA variations in genes that are associated with phenotypes that do not match the person being tested. Such variants are difficult to interpret.

Individual versus family studies are relevant, as family data allow for variants to be substantially filtered. This advantage must be weighed against the financial costs of studying families versus individuals. Furthermore, family studies are useless if an affected person is called unaffected or vice versa. Therefore, phenotyping family members is critical. For later-onset conditions, younger siblings may not be suitable for inclusion in an exome study unless their affected status can be determined unambiguously.

Data revisiting policies must be addressed. Genome-scale sequencing generates data for many genes beside those involved in the current diagnostic effort. The sequencing data are of potential use in the future care of the patient. Even though some mutated genes are not reported because they are not currently associated with any medical condition, future advances may implicate such a gene in a human disease. The person ordering the exome study should be aware of the data reuse policy of the testing facility. In the current testing environment, time-limited data reuse and/or reuse fees are increasingly common.

Early discussion with a genetic specialist is critical. Genetic counseling should be sought before an exome study is sent rather than after the results become available. Proper consent for exome studies is an involved process, including information about disease risk factors, unrelated medical conditions, carrier states and cancer susceptibility. Consented individuals should be given the opportunity to consider which types of results they would like to have returned.

Anticipating findings that are difficult to use clinically is an important part of counseling. The problem of variants of unknown significance is well known for any type of genetic testing. Genome-scale sequencing amplifies this problem to include a wide variety of results that are difficult to use for medical decision making. Depending on the breadth of analysis and the resulting clinical report, different numbers of such findings will be returned to the ordering physician. Discussing such variants with families can be difficult; counseling families about the likelihood of receiving this type of result before testing is performed can help the family to cope when the report is returned (see Chapter 77).

When used as a gene panel, ES rules in but does not rule out. An exome study is a cost-effective way to test many genes at one time. However, there can be variation in coverage of any given exon among exome datasets. Therefore, even though exome studies are a powerful tool for variant discovery, they are not always sufficient to exclude variants in a panel of genes. With careful analysis involving laboratory validation on many similarly processed individuals, the exome coverage of any given gene can be assessed. However, commercial/clinical testing facilities may be unwilling to perform such an analysis when a large set of genes needs to be considered. Therefore, there is still a role for the use of a gene panel when the index of suspicion is high for a disorder caused by 1 of a large group of genes. Cerebellar ataxia and hereditary spastic paraparesis are examples.

Providing information to the testing facility improves the chances of a diagnosis. ES interpretation will benefit substantially from the incorporation of accurate and detailed clinical information about the presenting phenotype. The more clinical information that is provided to the testing lab, the more specific and useful the clinical report will be.

GENE FUNCTION STUDIES

Despite filtering for frequency and predicted deleteriousness, a variant identified by genomic sequencing cannot be interpreted as the cause of an individual’s disease unless it has been previously demonstrated to cause a disease with a similar phenotype. To prove causality, medical genetics relies upon association (the recurrence of mutations within a gene among individuals with a similar phenotype). For rare diseases, there may be too few affected patients to demonstrate a statistically-significant association. In this setting, other evidence will be required to connect a specific genetic variant with an isolated phenotype. One approach is to accumulate additional diagnostic data about the patient that can be used to prioritize genetic variants (phenotype ontologies, metabolomics, glycomics, proteomics, and lipidomics). A second approach is to develop models that recapitulate the disease in question, such as mice, zebrafish, fruit flies, yeast, and cultured cells. Third, the variant in question can be linked to a biologic process or pathway that is known to cause a similar phenotype when disturbed. Finally, standardized and correlated phenotypic and genomic data are deposited into a database to identify other individuals with a similar phenotype and mutations in the same gene.

Physicians may apply their past biases to a group of variants that could be disease causing, but this is often misleading. A standardized computational approach would be preferable. For example, the Human Phenotype Ontology will standardize the description of a disease and, because the descriptors have been mapped to other human diseases and to mutant model organisms, will identify possible candidate genes and genetic networks for causing the disease. Similarly, untargeted laboratory screening tests provide an unbiased survey of patient cellular biology and physiology and a more informed prioritization of variants causing the patient’s disease.

The ultimate proof of causality is to ameliorate the disease process by correcting the genetic defect, and this can sometimes be demonstrated in a model system that recapitulates the human disease. If model systems fail to identify the genetic cause of an individual’s disease, one must search for other patients with a similar phenotype and mutations in the same gene. This can be accomplished using public databases that are interpreted using strict statistical and biologic standards.

PEDIATRIC ISSUES

During its first 4 yr, the UDP at NIH received 500 pediatric applications. In >10% of cases, more than 1 family member, usually a sibling, was similarly affected. There were 2 peaks in the age distribution of the children: 1 at 4–5 yr, reflecting patients with congenital disorders, and 1 at 16–18 yr representing disorders with symptom onset at early school age. The majority of applicants had been on a diagnostic odyssey for more than 5 yr. Of the 200 pediatric cases accepted, 175 were
evaluated to date and 25% received a diagnosis. Of the diagnoses, half were obtained using conventional diagnostic methods, including clinical suspicion with molecular confirmation, biochemical testing with molecular confirmation, or radiographic interpretation. In the remainder of cases the diagnosis was arrived at using SNP analysis and next-generation sequencing; all of these were rare diseases.

Pediatric medical records require attention to what has and what has not been completed previously. The electronic medical record is an important tool for medical practice, but copy forward functions can perpetuate errors, such as reports of normal testing when in fact the test was recommended or ordered but cancelled. Repetitive copying also fosters sloppiness in critical thinking, failure to take an adequate history, and missing the nuances of symptom progression. A history and physical examination should be performed anew and all prior testing results confirmed via copies of original laboratory reports.

Prolonged and painful procedures should be performed under sedation, but the risks associated with sedation must be weighed against the value of the information and samples to be obtained (see Table 83-2).

CONSIDERATIONS FOR FAMILIES OF UNDIAGNOSED CHILDREN

When a child comes to a genetics clinic for evaluation the parents want to know:

- What does my child have? (diagnosis)
- Why did it happen? (etiology/inheritance)
- What will happen in the future? (natural history)
- Is there a treatment? (therapy)
- Could the same thing happen to other family members? (recurrence risk)

The answers to all of these questions require an accurate diagnosis. The lack of a diagnosis also makes both the family and the physician uncomfortable, raises suspicion among relatives and acquaintances, and creates feelings of guilt about not having worked hard enough to find a diagnosis. As a consequence, families consult more and more specialists, and are often frustrated with the lack of coordination among providers. It is helpful for the family to save copies of every test and every visit from each institution and compile them in a binder for travel among institutions. A 2-3 page narrative summarizing the child’s history, medications, list of healthcare providers with contact information, main medical issues, level of functioning on well days and sick days, and interventions that worked in the past, can be invaluable in an emergency room setting. An electronic copy is easily updated. Parents can always be the best advocates for their child, particularly an undiagnosed child.

Recommendations to parents of an undiagnosed child are similar to those that apply to any child with chronic illness:

- Keep copies of all records, electronic and otherwise, and organize them routinely, especially copies of original reports from “send-out” labs.
- Carry an updated emergency letter.
- Establish a medical home even if you obtain many second opinions.
- Find a physiatrist (rehabilitation medicine physician) to coordinate rehabilitative care.
- Be aggressive with the school system about services using, a legal advocate if necessary.
- Explore parent support groups for unknown disorders ( Syndromes Without a Name, National Organization for Rare Disorders).

- Periodically check with providers (especially geneticists) for new diagnoses reported in the medical literature.
- Carve out time for yourselves as caregivers by engaging extended family members or respite care services.
- Work at supporting and being attentive to well children in the family.
- For the very sick dying child, consider an autopsy as a final attempt to establish a diagnosis especially when there is a possibility of future pregnancies.

THE DIAGNOSTIC SPECTRUM

The extent of determining the diagnosis varies considerably, from that of recognizing a clinical entity, to a largely molecular diagnosis, or to one in which the entire pathogenesis is known. In addition to known disorders, SNP and ES analyses may also identify variants in genes that are candidates for causing a new disease.

One example of a diagnosis involves 2 brothers whose parents were first cousins. The brothers had an early-onset spastic ataxia-neuropathy syndrome, with lower-extremity spasticity, peripheral neuropathy, ptosis, oculomotor apraxia, dystonia, cerebellar atrophy, and progressive myoclonic epilepsy. A homozygous missense mutation (c.1847G>A; p.Y616C) in AFG3L2, which encodes a subunit of a mitochondrial protease, was identified by ES. The AFG3L2 protein can bind to another AFG3L2 molecule or to paraplegin. UDF collaborators in Germany used a yeast model system to demonstrate that the patients’ mutation affects the specific amino acid involved in the formation of both of these complexes. As a result, the brothers exhibited the signs and symptoms of a known AFG3L2 defect, autosomal dominant spinocerebellar ataxia type 28 (SCA28), and a known paraplegin defect, hereditary spastic paraplegia type 7 (SPG7). Other features of a mitochondrial disorder (oculomotor apraxia, extrapyramidal dysfunction, myoclonic epilepsy) were also present. The 2 brothers represent the first such cases in the world, and expand the phenotype of AFG3L2 disease.

A second example involves 2 siblings ages 5 and 10 yr with hypotonia, developmental delays, facial dysmorphisms, hearing loss, nystagmus, seizures, and atrophy on brain MRI. In this case, the leading clue was biochemical in nature, and genetic analysis confirmed the diagnosis. Urine thin-layer chromatography for oligosaccharides identified a strong band determined by mass spectrometry to consist of a tetrasaccharide containing 3 glucose and one mannose. This suggested a defect of glucosidase I, the first enzyme involved in endoplasmic reticulum trimming of N-linked glycoproteins from a high-mannose to a complex form. Mutation analysis confirmed compound heterozygous mutations in the glucosidase I gene, establishing the diagnosis of congenital disorder of glycosylation IIb; the 2 siblings were the second and third patients in the world with this disorder.

The genetic analysis of rare and undiagnosed diseases has also yielded a variety of unique phenotypes that very likely represent new diseases. When variants in multiple genes are candidates for causing such a disorder, functional studies are required to demonstrate causality. This was successfully accomplished for a new disorder of vascular calcification identified and elucidated through the UDP at the NIH and found to be caused by a genetic deficiency of CD73, an enzyme on the surface of vascular cells that converts adenosine monophosphate to adenosine and inorganic phosphate.

Many childhood conditions are caused by single-gene mutations that encode specific proteins. These mutations can result in the alteration of primary protein structure or the amount of protein synthesized. The function of a protein, whether it is an enzyme, receptor, transport vehicle, membrane component, or structural element, may be compromised or abolished. These hereditary biochemical disorders are termed \textit{inborn errors of metabolism} or \textit{inherited metabolic disorders}.

Most mutations are clinically inconsequential and represent polymorphic differences that set individuals apart (\textit{genetic polymorphism}). Some mutations produce disease states that range from very mild to lethal. Severe forms of these disorders usually become clinically apparent in the newborn period or shortly thereafter.

**COMMON CHARACTERISTICS OF GENETIC DISORDERS OF METABOLISM**

Although the manifestations of genetic metabolic disorders are quite variable, the following features are shared among most of these conditions:

1. The affected infant is normal at birth and becomes symptomatic later on in life. This differentiates these infants from those who appear sick at birth as a result of birth trauma, intrauterine insults, chromosomal abnormalities, or other genetic diseases.

2. The nature of the mutation that causes the dysfunction of the gene usually varies from family to family. This results in variation in severity of the phenotype in different families. An exception to this is found when a specific mutation has been preserved in an ethnic group primarily from inbreeding (the founder effect). An example is maple syrup urine disease in Old Order Mennonites in the United States (mainly in Lancaster County, PA), in whom all the affected infants have the same mutation and hence the same phenotype (see Chapter 85.6).

3. Mutations causing severe malfunction of the gene or its product result in clinical manifestations shortly after birth. In general, the earlier the appearance of clinical symptoms, the more severe the disease.

4. The majority of conditions are inherited as autosomal recessive traits. Therefore, a history of consanguinity in the parents or of an unexplained death of a family member in the neonatal period may raise the question of an inherited metabolic disease in the sick infant.

5. Most genetic metabolic conditions can be controlled successfully by some form of therapy, and a few can be potentially cured by the use of bone marrow or liver transplants. These patients can have a normal life if diagnosed and treated early, before irreversible damage to organs, especially to the brain, occurs. This underlines the importance of early diagnosis, which can be achieved through mass screening of all newborn infants.

**MASS SCREENING OF NEWBORN INFANTS**

Common characteristics of genetic metabolic conditions and the significance of early diagnosis make a strong argument for screening all newborn infants for the presence of these conditions. During the past half-century, methods have been developed to screen all infants inexpensively with accurate and fast-yielding results. Tandem mass spectrometry is the latest technical advance in the field. This method requires a few drops of blood to be placed on a filter paper and mailed to a central laboratory for assay. A large number of genetic conditions can be identified by this method when complemented by a few equally efficient assays for other specific disorders (Tables 84-1 and 84-2).

Severe forms of some of these diseases may cause clinical manifestations before the results of the newborn screening become available. It should also be noted that these methods may identify mild forms of inherited metabolic conditions, some of which may never cause clinical manifestations in the lifetime of the individual. Potential psychosocial implications of such findings can be drastic and deserve serious consideration. An example of this is 3-methylcrotonyl-coenzyme A carboxylase deficiency, which has been identified with unexpectedly high frequency in screening programs using tandem mass spectrometry. The majority of these children have remained asymptomatic (see Chapter 85.6).

**CLINICAL MANIFESTATIONS OF GENETIC METABOLIC DISEASES**

Physicians and other healthcare providers who care for children should familiarize themselves with early manifestations of genetic metabolic disorders, because (1) severe forms of some of these conditions may cause symptoms before the results of screening studies become available, and (2) the current screening methods, although quite extensive, identify a small number of all inherited metabolic conditions. In the newborn period, the clinical findings are usually nonspecific and similar to those seen in infants with sepsis. A genetic disorder of metabolism should be considered in the differential diagnosis of a severely ill newborn infant, and special studies should be undertaken if the index of suspicion is high (Fig. 84-1).

Signs and symptoms such as lethargy, poor feeding, convulsions, and vomiting may develop as early as a few hours after birth. Occasionally, vomiting may be severe enough to suggest the diagnosis of pyloric stenosis, which is usually not present, although it may occur simultaneously in such infants. Lethargy, poor feeding, convulsions, and coma may also be seen in infants with hypoglycemia (see Chapters 92 and 107) or hypocalcemia (see Chapters 51 and 571). Measurements of blood concentrations of glucose and calcium and response to intravenous injection of glucose or calcium usually establish these diagnoses. Some of these disorders have a high incidence in specific population groups. Tyrosinemia type 1 is more common among French-Canadians of Quebec than in the general population. Therefore, knowledge of the ethnic background of the patient may be helpful in diagnosis. \textit{Physical examination} usually reveals nonspecific findings; most signs are related to the central nervous system. Hepatomegaly is a common finding in a variety of inborn errors of metabolism. Occasionally, a peculiar odor may offer an invaluable aid to the diagnosis (Table 84-3). A physician caring for a sick infant should smell the patient and the patient’s excreta; for example, patients with maple syrup urine disease have the unmistakable odor of maple syrup in their urine and on their bodies.

Occasionally, the onset of a genetic metabolic condition may occur months or years after birth. These children usually have mutations that render the gene partially nonfunctional. \textit{Clinical manifestations}, such as intellectual disability, motor deficits, developmental regression, convulsions, myopathy, recurrent emesis, and cardiomyopathy, in a child beyond the neonatal period should raise the possibility of an inherited
metabolic disease. There may be an episodic or intermittent pattern, with episodes of acute clinical manifestations separated by periods of seemingly disease-free states. The episodes are usually triggered by stress or a nonspecific catabolic insult such as an infection. The child may die during one of these acute attacks. A genetic disorder of metabolism should be considered in any child with 1 or more of the following manifestations: unexplained intellectual disability, developmental delay or regression, motor deficits or adventitious movements (e.g., dystonia, choreoathetosis), convulsions, unusual odor (particularly during an acute illness); intermittent episodes of unexplained vomiting, acidosis, mental deterioration, psychotic behavior or coma; hepatomegaly; renal stones; muscle weakness; or cardiomyopathy. For example, urea cycle defects may present with confusion, behavioral disturbances, catatonia, hallucinations, psychosis, or depression. Cataract may also be seen in disorders of folate metabolism, porphyria, Wilson disease, and some storage diseases. Severe seizures may be noted in molybdenum cofactor deficiency, biotinidase deficiency, neuronal ceroid lipofuscinos, nonketotic hyperglycinemia, or creatine deficiency.

Diagnosis usually requires a variety of specific laboratory studies. Measurements of serum concentrations of ammonia, bicarbonate, and pH are often very helpful initially in differentiating major causes of genetic metabolic disorders (see Fig. 84-1). Elevation of blood ammonia is usually caused by defects of urea cycle enzymes. Infants with elevated blood ammonia levels from urea cycle defects commonly have normal serum pH and bicarbonate values; without measurement of blood ammonia, they may remain undiagnosed and succumb to their disease. Elevation of serum ammonia is also observed in some infants with certain organic acidemias. These infants are severely acidic because of accumulation of organic acids in body fluids.
Figure 84-1 Initial clinical approach to a full term newborn infant with a suspected genetic metabolic disorder. This schema is a guide to the elucidation of some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases.

When blood ammonia, pH, and bicarbonate values are normal, other aminoacidopathies (such as hyperglycinemia) or galactosemia should be considered; galactosemic infants may also manifest cataracts, hepatomegaly, ascites, and jaundice.

**TREATMENT**

The majority of patients with genetic disorders of metabolism respond to 1 or all of the following treatments:

1. Special diets play an important role in the treatment of affected children. Dietary changes should be tailored to the pathophysiology of the condition and vary greatly among disorders.

2. Peritoneal dialysis or hemodialysis for expeditious removal of accumulated noxious compounds. This is a very effective modality for treatment of the acute phase of the condition.

3. Administration of the deficient metabolite.

4. Administration of the cofactor or coenzyme to maximize the residual enzyme activity.

5. Activation of alternate pathways to reduce the noxious compounds accumulated because of the genetic mutation.

6. Administration of the deficient enzyme.

8. Liver transplantation.

The bone marrow and liver transplantation modalities have the potential to cure the metabolic abnormalities. Replacement of the mutant gene with a normal one (gene therapy) is still in the experimental phase.

Treatment of genetic disorders of metabolism is complex and requires medical and technical expertise. The therapeutic regimen often needs to be tailored to the individual patient because of large phenotypic variations in the severity of the disease, even within a single family. Providing education and support for the family is the key to successful long-term therapy. Even in patients with hopeless prognoses every effort should be made to establish correct diagnoses premortem as the autopsy results are often noncontributory to the diagnosis. Effective treatment is best achieved by a team of specialists (physician metabolic genetics specialist, nutritionist, geneticist, neurologist, and psychologist) in a major medical center.

Bibliography
Phenylalanine is an essential amino acid. Dietary phenylalanine not utilized for protein synthesis is normally degraded by way of the tyrosine pathway (Fig. 85-1). Deficiency of the enzyme phenylalanine hydroxylase (PAH) or of its cofactor tetrahydrobiopterin (BH₄) causes accumulation of phenylalanine in body fluids and in the brain.

Hyperphenylalaninemia depends on the degree of enzyme deficiency and may vary from very high plasma concentrations (>20 mg/dL or >1,200 µmole/L, classic phenylketonuria) to mildly elevated levels (2-10 mg/dL or 120-600 µmole/L, mild hyperphenylalaninemia). In affected infants with plasma concentrations >20 mg/dL, excess phenylalanine is metabolized to phenylketones (phenylpyruvate and phenylacetate; see Fig. 85-1) that are excreted in the urine, giving rise to the term phenylketonuria (PKU). These metabolites have no role in pathogenesis of central nervous system (CNS) damage in patients with PKU; their presence in the body fluids simply signifies the severity of the condition. The term hyperphenylalaninemia implies lower plasma levels (<20 mg/dL) of phenylalanine. The brain is the main organ affected by hyperphenylalaninemia. The CNS damage in affected patients is caused by the elevated concentration of phenylalanine in brain tissue. The high blood levels of phenylalanine in PKU saturate the transport system across the blood–brain barrier causing inhibition of the cerebral uptake of other large neutral amino acids such as tyrosine and tryptophan. The exact mechanism of damage caused by elevated levels of intracerebral phenylalanine remains elusive. There have been a few adults with classic PKU and normal intelligence who have
never been treated with a phenylalanine-restricted diet. Phenylalanine content of the brain in these individuals was found to be close to that of normal subjects when studied by magnetic resonance spectroscopy (MRS).

**CLASSIC PHENYLKETONURIA**

Severe hyperphenylalaninemia (plasma phenylalanine levels >20 mg/dL), if untreated, invariably results in the development of signs and symptoms of classic PKU, except in rare unpredictable cases (see above).

**Clinical Manifestations**

The affected infant is normal at birth. Profound intellectual disability develops gradually if the infant remains untreated. Cognitive delay may not be evident for the first few months. In untreated patients, 50-70% will have an IQ below 35, and 88-90% will have an IQ below 65. Only 2-5% of untreated patients will have normal intelligence. Many patients require institutional care if the condition remains untreated. Vomiting, sometimes severe enough to be misdiagnosed as pyloric stenosis, may be an early symptom. Older untreated children become hyperactive with autistic behaviors, including purposeless hand movements, rhythmic rocking, and athetosis.

The infants are lighter in their complexion than unaffected siblings. Some may have a seborrheic or eczematoid rash, which is usually mild and disappears as the child grows older. These children have an unpleasant odor of phenylacetic acid, which has been described as musty or mousey. Neurologic signs include seizures (approximately 25%), spasticity, hyperreflexia, and tremors; more than 50% have electroencephalographic abnormalities. Microcephaly, prominent maxillae and sometimes flat or high arched palate, widely spaced teeth, enamel hypoplasia, and growth retardation may be other common findings in untreated children. The clinical manifestations of classic PKU are rarely seen in those countries in which neonatal screening programs for the detection of PKU are in effect.

**Nonphenylketonuria Hyperphenylalaninemas (Milder Forms of Hyperphenylalaninemia)**

In any screening program for PKU, a group of infants is identified in whom initial plasma concentrations of phenylalanine are above normal (i.e., >2 mg/dL or 120 µmole/L) but <20 mg/dL (1,200 µmole/L). These infants do not excrete phenylketones. Patients with non-PKU
Hyperphenylalaninemia may still require dietary therapy, depending on their untreated plasma phenylalanine level. Attempts have been made to classify these patients in different subgroups depending on the degree of hyperphenylalaninemia, but such a practice has little clinical or therapeutic advantage. The possibility of deficiency of BH₄ should be investigated in all infants with the milder forms of hyperphenylalaninemia (see below).

**Diagnosis**

Because of the gradual and nonspecific nature of early clinical symptoms such as vomiting, developmental delay, or eczematoid rash, hyperphenylalaninemia is usually diagnosed through newborn screening in all developed countries. In infants with positive screening results, diagnosis should be confirmed by quantitative measurement of plasma phenylalanine concentration. Identification and measurement of phenylketones in the urine has no place in any screening program. In countries and places where such programs are not in effect, identification of phenylketones in the urine by ferric chloride may offer a simple test for diagnosis of infants with developmental and neurologic abnormalities. Once the diagnosis of hyperphenylalaninemia is established, additional studies for BH₄ metabolism should be performed to rule out BH₄ deficiency as the cause of hyperphenylalaninemia (see below).

**Neonatal Screening for Hyperphenylalaninemia**

Effective and relatively inexpensive methods for mass screening of newborn infants have been developed and are used in the United States and several other countries. A few drops of blood, which are placed on a filter paper and mailed to a central laboratory, are used for assay. The bacterial inhibition assay of Guthrie, which was the first method used for this purpose, has been replaced by more precise and quantitative methods (fluorometric and tandem mass spectrometry). The method of choice is tandem mass spectrometry, which identifies all forms of hyperphenylalaninemia with a low false-positive rate and excellent accuracy and precision. The addition of the phenylalanine:tyrosine molar ratio has further reduced the number of false-positive results. Diagnosis must be confirmed by measurement of plasma phenylalanine concentration. Blood phenylalanine in affected infants with PKU may rise to diagnostic levels as early as 4 hr after birth, even in the absence of protein feeding. It is recommended that the blood for screening be obtained in the first 24-48 hr of life after feeding protein to reduce the possibility of false-negative results, especially in the milder forms of the condition.

**Treatment**

The mainstay of treatment of PKU is a low-phenylalanine diet. The general consensus is to start diet treatment immediately in patients with blood phenylalanine levels above 10 mg/dL (600 µmole/L). Most physicians also advocate phenylalanine-restricted diet in patients with mild hyperphenylalaninemia whose levels are persistently above 6 mg/dL (360 µmole/L). It is generally accepted that infants with persistent (more than a few days) plasma levels of phenylalanine ≥6 mg/dL (360 µmole/L) should be treated with a phenylalanine-restricted diet similar to that for classic PKU. The goal of therapy is to reduce phenylalanine levels in the plasma and brain. Formulas free of or low in phenylalanine are commercially available. The diet should be started as soon as the diagnosis is established. Because phenylalanine is not synthesized endogenously, small amounts of phenylalanine should be added to the diet to prevent phenylalanine deficiency. Dietary deficiency of this amino acid is manifested by lethargy, failure to thrive, anorexia, anemia, rashes, diarrhea, and even death; moreover, tyrosine becomes an essential amino acid in this disorder and its adequate intake must be ensured. Special food items low in phenylalanine are commercially available for dietary treatment of affected children and adults. There is no firm consensus concerning optimal level of blood phenylalanine in affected patients either across different countries or among treatment centers in the United States. In 2001, the National Institutes of Health Consensus Development Panel recommended that plasma phenylalanine levels be maintained between 2 and 6 mg/dL in neonates through 12 yr of age and between 2 and 15 mg/dL in older individuals. Given that brain development continues in adolescence and even in adulthood, maintenance of lower plasma phenylalanine levels (2-10 mg/dL) has been strongly encouraged even after 12 yr of age. The duration of diet therapy is also controversial. Discontinuation of therapy, even in adulthood, may cause deterioration of IQ and cognitive performance. The current recommendation from the 2001 National Institutes of Health Consensus Development Panel is that all patients be kept on a phenylalanine-restricted diet for life. Lifelong adherence to a low phenylalanine diet is extremely difficult. Patients, who maintain good control as children but discontinue the phenylalanine-restricted diet as teenagers or adults, may experience significant difficulties with executive function concentration, emotional liability, and depression. Executive dysfunction may also occur in early treated children in spite of diet treatment.

Given the difficulty of maintaining a strict low-phenylalanine diet, there are continuing attempts to find other modalities for treatment of these patients. Administration of large neutral amino acids (LNAA)s is another approach to diet therapy. LNAA{s (tyrosine, tryptophan, arginine, leucine, isoleucine, valine, methionine, histidine, lysine, threonine, and phenylalanine) share the same transporter protein (LNAA type 1, LAT-1) for transit through the intestinal cell membrane and blood–brain barrier. Binding of LNAA to the transporter protein is a competitive process. The rationale for use of LNAA is that these molecules compete with phenylalanine for transport across the blood–brain barrier; therefore, large concentrations of other LNAA{s in the intestinal lumen and in the blood reduce the uptake of phenylalanine into bloodstream and the brain. Clinical trials to establish the efficacy of this treatment are lacking at this time. Oral administration of BH₄, the cofactor for PAH, may result in reduction of plasma levels of phenylalanine in some patients with PAH deficiency. Plasma levels of phenylalanine in these patients may decrease enough to allow for considerable modification of their dietary restriction. In very rare cases, the diet may be discontinued because the phenylalanine levels remain under 6 mg/dL. The response to BH₄ cannot be predicted consistently on the basis of genotype, especially in compound heterozygous patients. Sapropterin dihydrochloride (Kuvan), a synthetic form of BH₄, which acts as a cofactor in patients with residual PAH activity, is approved by the FDA to reduce phenylalanine levels in PKU. At a dose of 10 mg/kg/day, it reduces phenylalanine levels in up to 40% of patients. Preliminary trials with recombinant phenylalanine ammonia lyase have been encouraging and demonstrated reduced blood levels of phenylalanine during treatment.

Low mineral bone density and osteopenia have been reported in affected individuals of all ages. Although inadequate intake of natural proteins seems to be the major culprit, the exact pathogenesis of this sequela remains unclear.

Long-term care of patients with PKU is best achieved by a team of experienced professionals (metabolic specialist, nutritionist, and psychologist) in a regional treatment center.

**Pregnancy in Women with Hyperphenylalaninemia (Maternal Phenylketonuria)**

Pregnant women with hyperphenylalaninemia who are not on a phenylalanine-restricted diet have a very high risk of having offspring with intellectual disability, microcephaly, growth retardation, congenital malformations, and congenital heart disease. These complications are directly correlated with elevated maternal blood phenylalanine levels during pregnancy. Prospective mothers who have been treated for hyperphenylalaninemia should be maintained on a phenylalanine-restricted diet before and during pregnancy; the best observed outcomes occur when strict control of maternal blood phenylalanine concentration is instituted before pregnancy or by 8 wk of gestation at the latest. The currently recommended phenylalanine concentrations are between 2 and 6 mg/dL (120-360 µmole/L) throughout the pregnancy. All women with hyperphenylalaninemia who are of childbearing age should be counseled properly as to the risk of the just described congenital anomalies in their offspring.
HYPERPHENYLALANINEMIA CAUSED BY DEFICIENCY OF THE COFACTOR TETRAHYDROBIOPTERIN

In 1-3% of infants with hyperphenylalaninemia, the defect resides in 1 of the enzymes necessary for production or recycling of the cofactor BH4 (see Fig. 85-1). If these infants are misdiagnosed as having PKU, they may deteriorate neurologically despite adequate control of plasma phenylalanine. BH4 is synthesized from guanosine triphosphate (GTP) through several enzymatic reactions (see Fig. 85-1). In addition to acting as a cofactor for PAH, BH4 is also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are involved in the biosynthesis of dopamine (Fig. 85-2) and serotonin (see Fig. 85-5), respectively. Therefore, patients with hyperphenylalaninemia as a result of BH4 deficiency also manifest neurologic findings related to deficiencies of the neurotransmitters dopamine and serotonin. Four enzyme deficiencies leading to defective BH4 formation cause hyperphenylalaninemia with concomitant deficiencies of dopamine and serotonin. These include autosomal recessive GTP cyclohydrolase deficiency, pericarbinolamine dehydratase deficiency, dihydropteridine reductase deficiency, and 6-pyruvoyl tetrahydropterin synthase deficiency. More than half of the reported patients have had a deficiency of 6-pyruvoyl tetrahydropterin synthase. Autosomal dominant forms of GTP deficiency and sepiapterin reductase deficiency result in deficiencies of neurotransmitters without hyperphenylalaninemia (see Chapter 85.11 and Fig. 85-1).

Clinical Manifestations

Infants with cofactor deficiency are identified during screening programs for PKU because of evidence of hyperphenylalaninemia. Plasma phenylalanine levels may be as high as those in classic PKU or in the range of milder forms of hyperphenylalaninemia. However, the clinical manifestations of the neurotransmitter disorders differ greatly from those of PKU. Neurologic symptoms of the neurotransmitter disorders often manifest in the first few months of life and include extrapyramidal signs (choreoathetotic or dystonic limb movements, axial and truncal hypotonia, hypokinesia), feeding difficulties, and autonomic abnormalities. Intellectual disability, seizures, hypersalivation, and swallowing difficulties are also seen. The symptoms are usually progressive and often have a marked diurnal fluctuation. Prognosis and outcome strongly depend on the age at which the diagnosis is made and treatment is introduced, but also on the specific nature of the mutation and resulting enzyme defect.

Diagnosis

Despite the low incidence of BH4 defects, all newborns with hyperphenylalaninemia detected through newborn screening should be screened for BH4 defects.

BH4 deficiency and the responsible enzyme defect may be diagnosed by the following studies:

1. Measurement of neopterin (oxidative product of dihydroleopterin triphosphate) and bipterin (oxidative product of dihydropterin and BH4) in body fluids, especially urine (see Fig. 85-1). In patients with GTP cyclohydrolyase deficiency, urinary excretion of both neopterin and bipterin is very low. In patients with 6-pyruvoyl tetrahydropterin synthase deficiency, there is a marked elevation of neopterin excretion and a concomitant decrease in bipterin excretion. In patients with dihydropteridine reductase deficiency, neopterin is normal, but bipterin is very high. Excretion of bipterin increases in this enzyme deficiency because the quinonoid dihydrobipterin cannot be recycled back to BH4. Patients with pericarbinolamine dehydratase deficiency excrete 7-bipterin (an unusual isomer of bipterin) in their urine. In addition, examination of cerebrospinal fluid (CSF) reveals decreased levels of dopamine, serotonin, and their metabolites in all patients with BH4 deficiency (see Chapter 85.11).

2. BH4 loading test. An oral dose of BH4 (20 mg/kg) normalizes plasma phenylalanine and phenylalanine:tyrosine ratio in patients with BH4 deficiency within 4-8 hr. The blood phenylalanine should be elevated (>400 μmol/L) to enable interpretation of the results. This may be achieved by discontinuing diet therapy for 2 days before the test or by administering a loading dose of phenylalanine (100 mg/kg) 3 hr before the test. In BH4-responsive PKU caused by PAH deficiency, blood phenylalanine levels may decrease during the BH4 loading test, but increase later even with BH4 supplementation. Patients who demonstrate phenylalanine levels within normal range over at least a week without a phenylalanine-restricted diet can be continued on BH4 supplementation as the sole treatment for the hyperphenylalaninemia. However, it is imperative that plasma

![Figure 85-2 Other pathways involving tyrosine metabolism. PKU* indicates hyperphenylalaninemia caused by tetrahydrobiopterin (BH4) deficiency (see Fig. 85-1). HVA, homovanillic acid; VMA, vanillylmandelic acid. Enzymes: (1) Tyrosine hydroxylase (TH), (2) aromatic l-amino acid decarboxylase (AADC), (3) dopamine β-hydroxylase (DβH), (4) phenylethanolamine-N-methyltransferase (PNMT), (5) catechol-O-methyltransferase (COMT), (6) monoamine oxidase (MAO).](image-url)
phenylalanine levels are monitored prospectively to ensure that phenylalanine levels remain within the normal range.

3. Enzyme assay. The activity of dihydropteridine reductase can be measured in the dry blood spots on the filter paper used for screening purposes. 6-Pyruvoyltetrahydropterin synthase activity can be measured in the liver, kidneys, and erythrocytes. Carbinolamine dehydratase activity can be measured in the liver and kidneys. GTP cyclohydrolase activity can be measured in the liver and in cytokine (interferon-γ) stimulated mononuclear cells or fibroblasts (the enzyme activity is normally very low in unstimulated cells).

4. Genetic test. Mutation analysis and deletion/duplication studies are clinically available for all these enzyme defects and help to confirm the diagnosis.

Treatment
The goals of therapy are to correct hyperphenylalaninemia and to restore neurotransmitter deficiencies in the CNS. The control of hyperphenylalaninemia is important in patients with cofactor deficiency, because high levels of phenylalanine cause intellectual disability and also interfere with the transport of neurotransmitter precursors (tyrosine, tryptophan) into the brain. Plasma phenylalanine should be maintained as close to normal as possible (<6 mg/dL). This can be achieved by oral supplementation of BH4 (5-20 mg/kg/day). Sapropterin dihydrochloride (Kuvan), a synthetic form of BH4 is commercially available, although it is expensive.

Lifelong supplementation with neurotransmitter precursors such as L-dopa and 5-hydroxytryptophan, along with carbidopa to inhibit degradation of L-dopa before it enters the CNS, is necessary in most of these patients even when treatment with BH4 normalizes plasma levels of phenylalanine. BH4 does not readily enter the brain to restore neurotransmitter production. To minimize untoward side effects (especially L-dopa–induced dyskinesia), the treatment should be started with low doses of L-dopa/carbidopa and 5-hydroxy tryptophan, and should be adjusted based on response to therapy and clinical improvement for each individual patient. Supplementation with folinic acid is also recommended in patients with dihydropteridine reductase deficiency. Unfortunately, attempting to normalize neurotransmitter levels using neurotransmitter precursors usually does not fully resolve the neurologic symptoms as a result of the inability to attain normal levels of BH4 in the brain. Patients often demonstrate intellectual disability, fluctuating abnormalities of tone, eye movement abnormalities, poor balance and coordination, decreased ability to ambulate, and seizures in spite of supplementation with neurotransmitter precursors.

Hyperprolactinemia occurs in patients with BH4 deficiency and may be the result of hypothalamic dopamine deficiency. Measurement of serum prolactin levels may be a convenient method for monitoring adequacy of neurotransmitter replacement in affected patients.

Some drugs, such as trimethoprim sulfamethoxazole, methotrexate, and other antileukemic agents, are known to inhibit dihydropteridine reductase enzyme activity and should be used with great caution in patients with BH4 deficiency.

Genetics and Prevalence
All defects causing hyperphenylalaninemia are inherited as autosomal recessive traits. The prevalence of PKU in the United States is estimated at 1 in 14,000 to 1 in 20,000 live births. The prevalence of non-PKU hyperphenylalaninemia is estimated at 1 in 50,000 live births. The condition is more common in whites and Native Americans and less prevalent in African-Americans, Hispanics, and Asians.

The gene for PAH is located on chromosome 12q23.2 and many disease-causing mutations have been identified in different families. The majority of patients are compound heterozygotes for 2 different mutant alleles. The gene for 6-pyruvoyltetrahydropterin synthase (PTS), the most common cause of BH4 deficiency, resides on chromosome 11q23.1, the gene for dihydropteridine reductase (QDPR) is located on chromosome 4p15.2, and those of carbinolamine dehydratase (PCBD1) and GTP cyclohydrolase (GCH1) are on 10q22.1 and 14q22.2, respectively. Many disease-causing mutations of these genes have been identified. Prenatal diagnosis is possible using specific genetic probes in cells obtained from biopsy of the chorionic villi.

TETRAHYDROBIOPTERIN DEFECTS WITHOUT HYPERPHENYLALANINEMIA
See Chapter 85.11.

Bibliography is available at Expert Consult.

85.2 Tyrosine
Grant A. Mitchell and Iraj Rezvani

Tyrosine is derived from ingested proteins or is synthesized endogenously from phenylalanine. It is used for protein synthesis and is a precursor of dopamine, norepinephrine, epinephrine, melatonin, and thyroxine. Excess tyrosine is metabolized to carbon dioxide and water (see Fig. 85-1). Hereditary causes of hypertyrosinemia include deficiencies of tyrosine aminotransferase, 4-hydroxyphenylpyruvate dioxygenase (4-HPPD), and fumarylacetoacetate hydratase. Acquired hypertyrosinemia may occur in severe hepatocellular dysfunction (liver failure), scurvy (vitamin C is the cofactor for 4-HPPD), and hyperthyroidism. Hypertyrosinemia is common in blood samples obtained soon after eating and in premature infants.

TYROSINEMIA TYPE I (TYROSINOSIS, HEREDITARY TYROSINEMIA, HEPATORENAL TYROSINEMIA)
This severe disease of the liver, kidney, and peripheral nerves is caused by a deficiency of the enzyme fumarylacetoacetate hydratase. Organ damage is believed to result from accumulation of metabolites of tyrosine degradation, especially fumarylacetocetate and succinylacetone.

Clinical Manifestations and Natural History
Untreated, the affected infant appears normal at birth and typically presents between 2 and 6 mo of age but rarely may become symptomatic in the 1st mo or appear healthy beyond the 1st yr of life. The earlier the presentation, the poorer the prognosis. The 1 yr mortality of untreated children, which is approximately 60% in infants who develop symptoms before 2 mo of age, decreases to 4% in infants who become symptomatic after 6 mo of age.

An acute hepatic crisis commonly heralds the onset of the disease and is usually precipitated by an intercurrent illness that produces a catabolic state. Fever, irritability, vomiting, hemorrhage, hepatomegaly, jaundice, elevated levels of serum transaminases, and hypoglycemia are common. An odor resembling boiled cabbage may be present, resulting from increased methionine metabolites. Most hepatic crises resolve spontaneously, but may progress to liver failure and death. Between the crises, varying degrees of failure to thrive, hepatomegaly, and coagulation abnormalities often persist. Cirrhosis and eventually hepatocellular carcinoma occur with increasing age. Carcinoma is unusual before 2 yr of age.

Episodes of acute peripheral neuropathy resembling acute porphyria occur in approximately 40% of affected children. These crises, often triggered by a minor infection, are characterized by severe pain, often in the legs, associated with extensor hypertonia of the neck and trunk, vomiting, paralytic ileus, and, occasionally, self-induced injuries of the tongue or buccal mucosa. Marked weakness and paralysis occur in about 30% of episodes, which may lead to respiratory failure requiring mechanical ventilation. Crises typically last 1-7 days but recovopa from paralytic crises can require weeks to months.

Renal involvement is manifested as a Fanconi-like syndrome with hyperphosphaturia, hypophosphatemia, normal anion gap metabolic acidosis, and vitamin D–resistant rickets. Nephromegaly and nephrocalcinosis may be present on ultrasound examination. Glomerular failure may occur in adolescents and older patients.
Bibliography

Hypertrophic cardiomyopathy and hyperinsulinism are seen in some infants.

**Laboratory Findings**

The presence of elevated levels of succinylacetone in serum and urine is diagnostic for tyrosinemia type I (see Fig. 85-1). In untreated patients, the blood level of α-fetoprotein is increased, often markedly, and liver-synthesized coagulation factors are decreased in most patients; serum levels of transaminases are often increased, with marked increases being possible during acute hepatic episodes. Serum concentration of bilirubin is usually normal but can be increased with liver failure. Increased levels of α-fetoprotein are present in the cord blood of affected infants, indicating intrauterine liver damage. Plasma tyrosine levels are usually elevated at diagnosis but this is a nonspecific finding and is dependent on dietary intake. Plasma levels of other amino acids, particularly methionine, may also be elevated in patients with liver damage. Hyperphosphaturia, hypophosphatemia, and generalized aminoaciduria may occur. The urinary level of 5-aminolevulinic acid is elevated because of inhibition of 5-aminolevulinic hydratase by succinylacetone.

**Diagnosis** is usually established by demonstration of elevated levels of succinylacetone in urine or blood. Neonatal screening for hyper-tyrosinemia detects only a minority of patients with tyrosinemia type I. Succinylacetone, which is now assayed by some neonatal screening programs, has higher sensitivity and specificity than tyrosine and is the preferred metabolite for screening. Tyrosinemia type I should be differentiated from other causes of hepatitis and hepatic failure in infants, including galactosemia, hereditary fructose intolerance, neonatal iron storage disease, giant cell hepatitis, and citrullinemia type II (see Chapter 85.12).

**Treatment and Outcome**

A diet low in phenylalanine and tyrosine can slow but does not halt the progression of the condition. The treatment of choice is nitisinone, which inhibits tyrosine degradation at 4-HPPD (see Fig. 85-1). This treatment prevents acute hepatic and neurologic crises. Although nitisinone stops or greatly slows disease progression, some pretreatment liver damage is not reversible. Therefore, patients must be followed for development of cirrhosis or hepatocellular carcinoma. On imaging, the presence of even a single liver nodule usually indicates underlying cirrhosis. Most liver nodules in tyrosinemic patients are benign but current imaging techniques do not accurately distinguish all malignant nodules. Liver transplantation is an effective therapy for tyrosinemia type I and alleviates the risk of hepatocellular carcinoma. The impact of nitisinone treatment on the need for liver transplantation is still under study but the greatest effect is in patients treated early, such as children detected by neonatal screening, prior to the development of clinical symptoms. In early-treated patients, nitisinone has greatly reduced the need for liver transplantation. At any age, nitisinone treatment eliminates the occurrence of acute episodes of liver failure and neurologic crises although they are at risk for impaired cognitive function. Because nitisinone treatment causes an increase in plasma tyrosine level, a diet restricted in tyrosine and phenylalanine is prescribed. Rarely, nitisinone-treated patients develop corneal crystals, presumably of tyrosine, which are reversible by strict dietary compliance. This finding, combined with observations of developmental delay in some patients with tyrosinemia type II who chronically have elevated tyrosine levels, suggest that a diet low in phenylalanine and tyrosine should be continued in patients treated with nitisinone. The dietary treatment of patients with tyrosine and phenylalanine restriction necessitates surveillance to ensure adequate intakes of other nutrients and amino acids.

**Genetics and Prevalence**

Tyrosinemia type I is inherited as an autosomal recessive trait. The gene for fumarylacetoacetate hydrolase (FAH) maps to chromosome 15q 25.1 and; numerous disease-causing mutations of the gene have been reported. DNA analysis is useful for molecular prenatal diagnosis if the familial mutations are known and for carrier testing in groups at risk for specific mutations such as French-Canadians from the Saguenay-Lac Saint-Jean region of Quebec. The prevalence of the condition is estimated to be 1 in 1,846 live births in the Saguenay-Lac Saint-Jean region and approximately 1 in 100,000 live births worldwide. But tyrosinemia type I is panethnic; lack of French-Canadian or Scandinavian ancestry does not exclude the diagnosis. Prenatal diagnosis is typically performed by measurement of succinylacetone in amniotic fluid, or if the familial mutations are known, by DNA analysis of amniocytes or of chorionic villi.

**TYROSINEMIA TYPE II (RICHNER-HANHART SYNDROME, OCULOCUTANEOUS TYROSINEMIA)**

This rare autosomal recessive disorder is caused by deficiency of tyrosine aminotransferase and results in palp and plantar hyperkeratosis, herpetiform corneal ulcers, and intellectual disability (see Fig. 85-1). **Ocular manifestations**, which may occur as early as 6 mo of age, include excessive tearing, redness, pain, and photophobia. Corneal lesions are presumed to be because of tyrosine deposition. In contrast to herpetic ulcers, corneal lesions in tyrosinemia type II stain poorly with fluorescein and often are bilateral. **Skin lesions**, which may develop later in life, include painful, nonpruritic hyperkeratotic plaques on the soles, palms, and fingertips. Intellectual disability, which occurs in approximately 50% of patients, is usually mild to moderate.

The principal laboratory finding in untreated patients is marked hypertyrosinemia (20-50 mg/dL; 1,100-2,750 μmol/L). Surprisingly, 4-hydroxyphenylpyruvic acid and its metabolites are also elevated in urine despite being downstream from the metabolic block (see Fig. 85-1). This is hypothesized to occur via the action of other transaminases in the presence of high tyrosine concentrations, producing 4-hydroxyphenylpyruvic acid in cellular compartments like the mitochondrion in which it cannot be further degraded. In contrast to tyrosinemia type I, liver and kidney function are normal, as are serum concentrations of other amino acids and succinylacetone. Tyrosinemia type II is caused by TAT gene mutations, causing deficiency of cytosolic tyrosine aminotransferase activity in liver.

**Diagnosis** of type II tyrosinemia is established by assay of plasma tyrosine concentration in patients with suggestive findings. Molecular diagnosis is possible. Assay of liver tyrosine aminotransferase activity requires a liver biopsy and is rarely indicated.

**Treatment** with a diet low in tyrosine and phenylalanine improves the biochemical abnormalities and can normalize the skin and eye. The claim that intellectual disability may be prevented by early diet therapy is reasonable and is consistent with some case reports. The gene for tyrosine aminotransferase (TAT) maps to chromosome 16q22.2 and several disease-causing mutations have been identified. About half of reported cases are of Italian descent.

**TYROSINEMIA TYPE III (PRIMARY DEFICIENCY OF 4-HYDROXYPHENYLPYRUVATE DIOXYGENASE [4-HPPD])**

Only a few cases have been reported; most were detected by amino acid chromatography performed for various neurologic findings. Age at presentation has been from 1-17 mo. Developmental delay, seizures, intermittent ataxia, and self-destructive behavior are reported; a causal link to 4-HPPD deficiency is not formally established. Liver and renal abnormalities are absent. Asymptomatic infants with 4-HPPD deficiency have been identified by neonatal screening for hypertyrosinemia.

The **diagnosis** is suspected in children with sustained moderate increases in plasma levels of tyrosine (typically 350-700 μmol/L on a normal diet) and the presence of 4-hydroxyphenylpyruvic acid and its metabolites in urine. Diagnosis may be refined by demonstrating the presence of mutations in the gene (HPD) for 4-HPPD on chromosome 12q42.31, or rarely, by demonstrating a low activity of 4-HPPD enzyme; the latter requires a liver biopsy and is not usually indicated.

Given the possible association with neurologic abnormalities, dietary reduction of plasma tyrosine levels is prudent. It is also logical...
to attempt a trial of vitamin C, the cofactor for 4-HPPD. The condition is inherited as an autosomal recessive trait.

**HAWKINSINURIA**

Certain missense mutations in the gene for 4-HPPD result in an abnormal enzyme activity. The mutant enzyme, incapable of normally oxidizing 4-hydroxyphenylpyruvate to homogentisic acid, forms an intermediate that reacts with cysteine to form the unusual organic acid hawkinsin ((2-L-cysteinyl-5-S-y1-1,4-dihydroxy-cyclohex-5-en-1-y1)acetic acid, named after the first affected family, Fig. 85.1); secondary glutathione deficiency may occur. Hawkinsinuria is inherited as an autosomal dominant trait and a few specific causative missense mutations have been identified. The same mutation, a substitution of threonine for the normal alanine codon at position 33 of the 4-HPPD gene, has been identified in unrelated patients with hawkinsinuria. The condition is, perhaps, more prevalent than once realized.

Individuals with this disorder are symptomatic only during infancy. The symptoms usually appear in the first few months of life; commonly after weaning from breastfeeding and with the introduction of a high-protein diet. Severe metabolic acidosis, ketosis, failure to thrive, mild hepatomegaly, and an unusual odor (described as like that of a swimming pool) are reported manifestations of this disorder. Mental development is usually normal.

Symptomatic infants and asymptomatic affected children and adults excrete hawkinsin, 4-hydroxyphenylpyruvic acid, and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids), 4-hydroxycyclohexyacetic acid and 5-oxoproline (owing to secondary glutathione deficiency) in their urine. The plasma tyrosine level, which is moderately elevated in the symptomatic infants, may become normal in the asymptomatic affected individuals. Treatment consists of a low-protein diet during infancy. Breastfeeding is encouraged. A trial with large doses of vitamin C (up to 1,000 mg/24 hr) is also recommended. The mutant enzyme is susceptible to inhibition by nitisinone; clinical studies showing the efficacy of this agent in symptomatic infants are lacking at this time, and the indications for its use are not known.

**TRANSIENT TYROSINEMIA OF THE NEWBORN**

In a small number of newborn infants, plasma tyrosine may be as high as 60 mg/dL (3,300 µmole/L) during the 1st 2 wk of life. Most affected infants are premature and are receiving high-protein diets. Transient tyrosinemia is felt to result from delayed maturation of 4-HPPD (see Fig. 85-1). Lethargy, poor feeding, and decreased motor activity are noted in some patients. Most are asymptomatic and are identified by a high blood phenylalanine or tyrosine level on routine screening. Laboratory findings include marked elevation of plasma tyrosine with a moderate increase in plasma phenylalanine. The finding of hypertyrosinemia differentiates this condition from PKU. 4-Hydroxyphenylpyruvic acid and its metabolites (see above) are present in the urine. Hypertyrosinemia usually resolves spontaneously in the 1st mo of life. It can be corrected promptly by reducing dietary protein to below 2 g/kg/24 hr and by administering vitamin C (200-400 mg/24 hr). Mild intellectual deficits have been reported in some infants who had this condition, but the causal relationship to hypertyrosinemia is not conclusively established.

**ALKAPTONURIA**

This rare (with an incidence of approximately 1 in 250,000 live births) autosomal recessive disorder is caused by a deficiency of homogentisic acid oxidase (homogentisate 1,2-dioxigenase). In alkaptonuria, large amounts of homogentisic acid are formed (see Fig. 85-1); secondary glutathione deficiency may occur. Alkaptonuria is inherited as an autosomal dominant trait and a few specific causative missense mutations have been identified. The same mutation, a substitution of threonine for the normal alanine codon at position 33 of the 4-HPPD gene, has been identified in unrelated patients with hawkinsinuria. The condition is, perhaps, more prevalent than once realized.

The main clinical manifestations of alkaptonuria consist of ochronosis and arthritis in adulthood. The only sign in children is a blackening of the urine on standing, caused by oxidation and polymerization of homogentisic acid. A history of gray- or black-stained diapers should suggest the diagnosis. This sign may never be noted; hence, diagnosis is often delayed until adulthood. Ochronosis, which is seen clinically as dark spots on the sclera or cartilage, results from the accumulation of the black polymer of homogentisic acid. Arthritis is another result of this deposition and can be disabling with advancing age. It involves the large joints (spine, hip, and knee) and is usually more severe in males. Like rheumatoid arthritis, the alkaptonuric arthritis has acute exacerbations, but the radiologic findings are typical of osteoarthritis, with characteristic narrowing of the joint spaces and calcification of the intervertebral discs. High incidence of heart disease (mitral and aortic valvulitis, calcification of the heart valves, and myocardial infarction) has been noted.

The *diagnosis* is confirmed by finding massive excretion of homogentisic acid on urine organic acid testing. Tyrosine levels are normal. The enzyme is expressed only in the liver and kidneys.

**Treatment** of the arthritis is symptomatic. Nitisinone efficiently reduces homogentisic acid production in alkaptonuria. If presymptomatic individuals are detected, treatment with nitisinone, combined with a phenylalanine- and tyrosine-restricted diet, seems reasonable, although no experience is available regarding long-term efficacy.

The gene for homogentisic acid oxidase (HGD) maps to chromosome 3q13.3. Several disease-causing mutations have been identified. Alkaptonuria is commonest in the Dominican Republic and Slovakia.

**TYROSINE HYDROXYLASE DEFICIENCY**

See Chapter 85.11.

**ALBINISM** (See also Chapters 622 and 653)

Albinism is caused by deficiency of melanin, the main pigment of the skin and eye (Table 85-1). Melanin is synthesized by melanocytes from tyrosine in a membrane-bound intracellular organelle, the melanosome. Melanocytes originate from the embryonic neural crest and migrate to the skin, eyes (choroid and iris), hair follicles, and inner ear. The melanin in the eye is confined to the iris stromal and retinal pigment epithelia, whereas in skin and hair follicles, it is secreted into the epidermis and hair shaft. Albinism can be caused by deficiencies of melanin synthesis, by some hereditary defects of melanosomes, or by disorders of melanocyte migration. Neither the biosynthetic pathway of melanin nor many facets of melanocyte cell biology are completely elucidated (see Fig. 85-2). The end products are 2 pigments: *pheomelanin*, which is a yellow-red pigment, and *eumelanin*, a brown-black pigment.

| Table 85-1 Classification of Major Causes of Albinism |
|-----------------|--------|-----------------|
| **TYPE**        | **GENE** | **CHROMOSOME**  |
| Oculocutaneous Albinism (OCA) |       |                 |
| OCA1 (tyrosinase deficient) | TYR    | 11q14-q21       |
| OCA1A (severe deficiency)   | TYR    | 11q14-q21       |
| OCA1B (mild deficiency)*    | TYR    | 11q14-q21       |
| OCA2 (tyrosinase positive)  | OCA2   | 15q12-q13       |
| OCA3 (Rufous, red OCA)      | TYRP1† | 9p23            |
| OCA4                        | SLC45A2| 5p13.3          |
| Hermansky-Pudlak syndrome   | HP51-9 | Different       |
| Chédiak-Higashi syndrome    | LYST   | 1q42.1          |
| Ocular Albinism (OA)         | OA     | Xp22.3          |
| OA1 (Nettleship-Falls type)  |        |                 |
| Localized Albinism           | KIT    | 4q12            |
| Piebaldism                   |        |                 |
| Waardenburg syndrome (WS1-WS4) | See text |                 |

*This includes Amish, minimal pigment, yellow albinism, and platinum and temperature-sensitive variants.

†Includes brown OCA.

‡Tyrosinase-related protein 1.
Clinically, primary albinism can be generalized or localized. Primary generalized albinism can be either ocular or oculocutaneous. Some syndromes feature albinism in association with platelet, immunological, or neurological dysfunction.

In generalized oculocutaneous albinism, hypopigmentation can be either complete or partial. Individuals with complete albinism do not develop either generalized (tanning) or localized (pigmented nevi) skin pigmentation.

The diagnosis of albinism is usually evident, but for some white children whose families are particularly light-skinned, normal variation may be a diagnostic consideration. Unlike patients with albinism, normal fair-skinned children progressively develop pigmentation with age, do not exhibit the eye manifestations of albinism, and have pigmentary development similar to other family members. The clinical diagnosis of oculocutaneous albinism, as opposed to other types of cutaneous hypopigmentation, requires the presence of characteristic eye findings.

The ocular manifestations of albinism include hypopigmentation of iris and retina with foveal hypoplasia along with, reduced visual acuity, refractive errors, nystagmus, alternating strabismus, and a red reflex (diffuse reddish hue of the iris produced during ophthalmoscopic or slit-lamp examination of the eye). There is also an abnormality in routing of the optic fibers at the chiasm. Unlike normally in pigmented individuals, in patients with albinism the majority of the nerve fibers from the temporal side of the retina cross to the contralateral hemisphere of the brain. This results in lack of biocular (stereoscopic) vision and depth perception, and in repeated switching of vision from eye to eye, causing alternating strabismus. This abnormality also causes a characteristic pattern of visual-evoked potentials. These findings are highly specific for albinism and can be used to formally establish the clinical diagnosis. Regular ophthalmologic follow-up is recommended for patients with oculocutaneous albinism; correction of refractive errors can maximize visual function. Normally the alternating strabismus does not result in amblyopia and does not require surgery.

Patients with albinism should be counseled to avoid UV radiation by wearing protective long-sleeved clothing and by using sunscreens with a sun protection factor rating above 30. All forms of oculocutaneous albinism are autosomal recessive traits.

Melanin is also present in the cochlea. Albino individuals may be more susceptible to ototoxic agents such as gentamicin.

Many clinical forms of albinism have been identified. Some of the seemingly distinct clinical forms are caused by different mutations of the same gene. Several genes located on different chromosomes are involved in melanogenesis (see Table 85-1). Attempts to differentiate types of albinism based on the mode of inheritance, tyrosinase activity, or the extent of hypopigmentation have failed to yield a comprehensive classification. The following classification is based on the distribution of albinism in the body and the type of mutated gene.

Mutation detection is clinically available for most albinism genes (see Table 85-1). Molecular diagnosis is of little use therapeutically in isolated albinism but can be helpful for precise genetic counseling of families.

**Oculocutaneous (Generalized) Albinism**

Lack of pigment is generalized, affecting skin, hair, and eyes. At least 4 genetically distinct forms of oculocutaneous albinism (OCA) have been identified: OCA1, OCA2, OCA3, and OCA4. The lack of pigment is complete in patients with OCA1 A; the other types may not be clinically distinguishable from one another. All affected individuals have oculocutaneous manifestations of albinism (see above). All forms are inherited as autosomal recessive traits.

**OCA1 (Tyrosinase-Deficient Albinism)**

The defect in these patients resides in the tyrosinase gene, **TYR**, located on chromosome 11q14.3. Many mutant alleles have been identified. Most affected individuals are genetic compounds, heterozygous for 2 different mutant alleles. A clinical clue to the diagnosis of OCA1 is complete lack of pigment at birth. The condition can be subdivided to OCA1 A and OCA1 B, based on enzyme activity and difference in clinical manifestations as a function of age.

**OCA1 A (Tyrosinase-Negative OCA)**

In these individuals, who have the most severe form of OCA, both **TYR** alleles have mutations that completely inactivate tyrosinase. Clinically, lack of pigment in the skin (milky white), hair (white hair), and eyes (red gray irides) is evident at birth and remains unchanged throughout life. They do not tan and do not develop pigmented nevi or freckles.

**OCA1 B**

These patients have **TYR** gene mutations that preserve some residual activity. Clinically they completely lack pigment at birth, but with age become light blond with light blue or hazel eyes. They develop pigmented nevi and freckles and they may tan. OCA1 B patients, depending on the degree of pigmentation, were once subdivided into different groups and thought to be genetically distinct.

**OCA2 (Tyrosinase-Positive OCA)**

This is the most common form of generalized OCA, particularly in African blacks. Clinically, the phenotype is highly variable; most patients demonstrate some pigmentation of the skin and eyes at birth and continue to accumulate pigment throughout their lives. The hair is yellow at birth and may darken with age. They have pigmented nevi and freckles and some may tan. They may be clinically indistinguishable from OCA1 B. Individuals with OCA2 however, have normal tyrosinase activity in hair bulbs. The defect is in the OCA2 gene which is homologous to the p (pink-eyed dilution) gene in the mouse. This gene produces the P protein, a melanosomal membrane protein. Patients with forms of Prader-Willi and Angelman syndromes caused by microdeletion of chromosome 15q12 that includes the OCA2 gene have mild pigmentary deficiency (see Chapter 81.8).

**OCA3 (Rufous Albinism)**

This form has been identified only in Africans, African-Americans, and natives of New Guinea. Patients have reddish hair and reddish brown skin as adults. The skin color is peculiar to this form. In the young, the coloration may resemble that of OCA1. Patients with OCA3 can make pheomelanin but not eumelanin. The mutation is in the tyrosinase-related protein 1 (**TYRP1**) gene (located on chromosome 9p23), the function of which is not well-understood.

**OCA4**

Similar manifestations to OCA3 (both in the skin and the eyes) have been observed in patients (mostly from Japan) with mutations in the **SLC45A2** (previously called **MATP**) gene located on chromosome 5p13.2.

**Ocular Albinism**

Ocular albinism (OA) is limited to the eye. All the eye findings of albinism (see above) are present. Most cases are X-linked (OA1).

**Ocular Albinism 1 (Nettleship-Falls Type)**

Only the hemizygous male has the complete manifestation. Segments of abnormal retinal pigmentation may be present in heterozygous females. An X-linked OA with late-onset sensorineural deafness has also been reported. The diagnosis of ocular albinism 1 (OA1) is evident in males with the features of albinism in the eye, normal skin pigmentation, and a positive family history suggestive of an X-linked recessive transmission. Mild hypopigmentation of the skin (compared to unaffected siblings) may be present. It is a nonprogressive disorder and the eye findings, in fact, often improve with age. In patients who are the first of their families to be affected, electron microscopic demonstration of characteristic mega melanosomes in skin biopsies or hair root specimens is useful, as is mutation analysis of the OA1 gene on chromosome Xp22.2.
Syndromic Forms of Generalized Albinism

Hermansky-Pudlak Syndrome
This group of autosomal recessive disorders is caused by mutations in 1 of 9 different genes located on different chromosomes, HPS1 to HPS9. Hermansky-Pudlak syndrome is suspected in patients with albinism and a bleeding diathesis. Disease subtype can be established with molecular studies.

The HPS genes are necessary for normal structure and function of lysosome-derived organelles, including melanosomes and platelet dense bodies. Patients have a tyrosinase-positive OCA of variable severity associated with platelet dysfunction (owing to the absence of platelet dense bodies). A ceroid-like material accumulates in tissues. Hermansky-Pudlak syndrome is most prevalent in 2 regions of Puerto Rico (type 1 in the northwest and type 3 in the central regions as a result of different founder effects). The cutaneous and ocular symptoms of albinism are present. Patients can develop epistaxis, postsurgical bleeding, or abundant menses. Bleeding time is prolonged but no other symptoms of albinism are present. The diagnosis is usually made after 3 yr of age, when subluxation of the ocular lens (ectopia lentis) occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive intellectual disability is common. Normal intelligence has been reported. In an international survey of more than 600 patients, IQ scores ranged from 10–135. Higher IQ scores are seen in vitamin B6–responsive patients. This condition is caused by a homozygous mutation in the PAX3 gene. Type 4 (WS4), associated with Hirschsprung disease, is heterogeneous; mutations in different genes (EDN3, EDNRB, or SOX10) have been identified in different patients.

Other causes of localized hypopigmentation are discussed in other chapters (e.g., hypomelanosis of Ito, see Chapters 81 and 653; and vitiligo, see Chapter 655).

Bibliography is available at Expert Consult.

85.3 Methionine

Iraj Rezvani and David S. Rosenblatt

The usual pathway for catabolism of methionine, an essential amino acid, produces S-adenosylmethionine, which serves as a methyl group donor for methylation of a variety of compounds in the body, and cysteine, which is formed through a series of reactions collectively called trans-sulfuration (Fig. 85-3).

HOMOCYSTINURIA (HOMOCYSTINEMIA)

Normally, most homocysteine, an intermediate compound of methionine degradation, is remethylated to methione. This methionine-sparing reaction is catalyzed by the enzyme methionine synthase, which requires a metabolite of folate acid (5-methyltetrahydrofolate) as a methyl donor and a metabolite of vitamin B12 (methylcobalamin), as well as S-adenosylcobalamin, as cofactors (see Fig. 85-3). Only approximately 20% of total homocysteine (and its dimer homocystine) is in free form in the plasma of normal individuals. The rest is bound to proteins as mixed disulfides. Three major forms of homocystinemia and homocystinuria have been identified.

Homocystinuria Caused by Cystathionine β-Synthase Deficiency (Classic Homocystinuria)

This is the most common inborn error of methionine metabolism. Approximately 40% of affected patients respond to high doses of vitamin B6 and usually have milder clinical manifestations than those who are unresponsive to vitamin B6 therapy. These patients possess some residual enzyme activity. Infants with this disorder are normal at birth. Clinical manifestations during infancy are nonspecific and may include failure to thrive and developmental delay. The diagnosis is usually made after 3 yr of age, when subluxation of the ocular lens (ectopia lentis) occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive intellectual disability is common. Normal intelligence has been reported. In an international survey of more than 600 patients, IQ scores ranged from 10–135. Higher IQ scores are seen in vitamin B6–responsive patients. Psychiatric and behavioral disorders have been observed in more than 50% of affected patients. Convulsions occur in approximately 20% of patients. Affected individuals with homocystinuria manifest skeletal abnormalities resembling those of Marfan syndrome (see Chapter 702); they are usually tall and thin, with elongated limbs and arachnodactyly. Scoliosis, pectus excavatum or carinatum, genu valgum, pes cavus, high-arched palate, and crowding of the teeth are commonly seen. These children usually have fair complexions, blue eyes, and a peculiar malar flush. Generalized osteoporosis, especially of the spine, is the main roentgenographic finding. Thromboembolic episodes involving both large and small vessels, especially those of the brain, are common and may occur at any age. Optic atrophy, paralysis, cor pulmonale, and severe hypertension (from renal infarcts) are among the serious consequences of thromboembolism, which is caused by...
Bibliography

changes in the vascular walls and increased platelet adhesiveness secondary to elevated homocysteine levels. The risk of thromboembolism increases after surgical procedures. Spontaneous pneumothorax and acute pancreatitis are rare complications.

Elevations of both methionine and homocysteine (or homocystine) in body fluids are the diagnostic laboratory findings. Freshly voided urine should be tested for homocystine because this compound is unstable and may disappear as the urine is stored. Cystine is low or absent in plasma. The diagnosis may be established by assay of the enzyme in liver biopsy specimens, cultured fibroblasts, or phytohemagglutinin-stimulated lymphocytes or by DNA analysis.

Treatment with high doses of vitamin B₆ (200-1,000 mg/24 hr) causes dramatic improvement in most patients who are responsive to this therapy. The degree of response to vitamin B₆ treatment may be different in different families. Some patients may not respond because of folate depletion; a patient should not be considered unresponsive to vitamin B₆ until folic acid (1-5 mg/24 hr) has been added to the treatment regimen. Restriction of methionine intake in conjunction with cysteine supplementation is recommended for patients who are unresponsive to vitamin B₆. The need for dietary restriction and its extent remains controversial in patients with vitamin B₆-responsive form. In some patients with this form, addition of betaine may obviate the need for any dietary restriction. Betaine (trimethylglycine, 6-9 g/24 hr for adults or 200-250 mg/kg/day for children) lowers homocysteine levels in body fluids by remethylating homocysteine to methionine (see Fig. 85-3); this may result in further elevation of plasma methionine levels. This treatment has produced clinical improvement (preventing vascular events) in patients who are unresponsive to vitamin B₆ therapy. Cerebral edema has occurred in a patient with vitamin B₆-nonresponsive homocystinuria and dietary noncompliance during betaine therapy. Administration of large doses of vitamin C (1 g/day) has improved endothelial function; long-term clinical efficacy is not known.

More than 100 pregnancies in women with the classic form of homocystinuria have been reported with favorable outcomes for both mothers and infants. The majority of infants were full-term and normal. Postpartum thromboembolic events occurred in a few mothers. All but 1 of the 38 affected male patients has had normal offspring.

The screening of newborn infants for classic homocystinuria has been performed worldwide and a prevalence of 1 in 200,000 to 1 in 350,000 live births has been estimated. The condition seems more common in New South Wales, Australia (1 in 60,000 live births), and Ireland. Early treatment of patients identified by the screening process has produced favorable results. The mean IQ of 16 patients with vitamin B₆-unresponsive form treated in early infancy was 94 ± 4. Dislocation of the lens seemed to be prevented in some patients.

---

**Figure 85-3** Pathways in the metabolism of sulfur-containing amino acids. Enzymes: (1) Methionine adenosyltransferase (MAT I/III), (2) glycine-N-methyltransferase, (3) adenosylhomocysteine hydrolase, (4) cystathionine synthase, (5) cystathionase, (6) sulfite oxidase, (7) betaine homocysteine methyltransferase, (8) methylene tetrahydrofolate reductase, (9) Methionine synthase (cblG).
Homocystinuria is inherited as an autosomal recessive trait. The gene for cystathionine β-synthase (CBS) is located on chromosome 21q22.3. Prenatal diagnosis is feasible by performing an enzyme assay of cultured amniotic cells or chorionic villi or by DNA analysis. Many disease-causing mutations (>150) have been identified in different families. The majority of affected patients are compound heterozygotes for 2 different alleles. Heterozygous carriers are usually asymptomatic; thromboembolic events and coronary heart disease are more common in these individuals than in the normal population.

**Homocystinuria Caused by Defects in Methylcobalamin Formation**

Methylcobalamin is the cofactor for the enzyme methionine synthase, which catalyzes remethylation of homocysteine to methionine. There are at least 7 distinct defects in the intracellular metabolism of cobalamin that may interfere with the formation of methylcobalamin. To better understand the metabolism of cobalamin, see methylmalonic acidemia (Fig. 85-4; see Chapter 85.6 and Fig. 85-3). The 7 defects are designated as cblC, cblD (including cblD variant 1), cblE (methionine synthase reductase), cblG (methionine synthase), and cblF, cblI, and cblX. Patients with cblI, cblD (not including those with cblD variant 1 or variant 2), cblE, cblF, and cblI X defects have methylmalonic acidemia in addition to homocystinuria, because formation of both adenosylcobalamin and methylcobalamin is impaired (See Chapter 85.6 for further information about these defects.).

Patients with cblI, cblG, and cblD variant 1 defects are unable to form methylcobalamin and develop homocystinuria without methylmalonic acidemia (see Fig. 85-4); fewer than 40 patients are known with each of these diseases.

The clinical manifestations are similar in patients with all of these defects. Vomiting, poor feeding, failure to thrive, hypotonia, seizures, and developmental delay may occur in the first few months of life. One patient with the cblG defect was not symptomatic (except for mild developmental delay) until she was 21 yr old when she developed difficulty in walking and numbness of the hands. Laboratory findings include megaloblastic anemia, homocystinuria, and hypermethioninemia. The presence of megaloblastic anemia differentiates these defects from homocystinuria due to methylentetrahydrofolate reductase deficiency (see below). The absence of hypermethioninemia differentiates both of these conditions from cystathionine β-synthase deficiency (see above). Renal artery thrombosis, hemolytic uremic syndrome, pulmonary hypertension and optic nerve atrophy have been reported in some patients with these defects.

**Diagnosis** is established by complementation studies performed in cultured fibroblasts. Prenatal diagnosis has been accomplished by studies in amniotic cell cultures. These conditions (cblI, cblG, and cblD variant 1) are inherited as autosomal recessive traits. The gene for cblI is MTRR, encoding methionine synthase reductase (located on chromosome 5p15.3-p15.2) and the gene for cblG is MTR, encoding methionine synthase (located on chromosome 1q43); cblD variant 1 is caused by mutations affecting the C-terminal of the MMADHC gene (located on chromosome 2q23.2). Several disease-causing mutations, including a common missense mutation (P1173L) in the MTR gene, have been described.

**Treatment** with vitamin B₁₂ in the form of hydroxycobalamin (1-2 mg/24 hr) is used to correct the clinical and biochemical findings. Results vary among both diseases and sibships.

Defects causing both homocystinuria and methylmalonic acidemias are discussed in Chapter 85.6.

**Homocystinuria Caused by Deficiency of Methylentetrahydrofolate Reductase**

This enzyme reduces 5,10-methylentetrahydrofolate to form 5-methyltetrahydrofolate, which provides the methyl group needed for remethylation of homocysteine to methionine (see Fig. 85-3).

The severity of the enzyme defect and the clinical manifestations varies considerably in different families. Clinical findings vary from apnea, seizure, microcephaly, coma, and death to developmental delay, ataxia, and motor abnormalities or even psychiatric manifestations. Premature vascular disease or peripheral neuropathy has been reported as the only manifestation of this enzyme deficiency in some patients. Adults with severe enzyme deficiency may even be completely asymptomatic. Exposure to the anesthetic nitrous oxide (which inhibits methionine synthase) in patients with methylentetrahydrofolate reductase (MTHFR) deficiency may result in neurologic deterioration and death.

**Laboratory findings** include moderate homocystinemia and homocystinuria. The methionine concentration is low or low normal. This finding differentiates this condition from classic homocystinuria caused by cystathionine β-synthase deficiency. Absence of megaloblastic anemia distinguishes this condition from homocystinuria caused by methylcobalamin formation (see above). Thromboembolism of vessels has also been observed in these patients. Diagnosis may be confirmed by the enzyme assay in cultured fibroblasts or leukocytes or by finding causal mutation in the MTHFR gene.

A number of polymorphisms have been described in the MTHFR gene. Two of these (677C → T and 1298A → C) may affect levels of plasma total homocysteine and have been studied as possible risk factors for a wide variety of medical conditions, ranging from birth defects to vascular disease and even cancer, Alzheimer disease, and death from leukemia. To date, the best data support a role for 677C → T polymorphism as a risk factor for neural tube defects. Although a clinical test for this polymorphism is widely available, its predictive value in any given individual has yet to be determined.

**Treatment** of severe MTHFR deficiency with a combination of folic acid, vitamin B₁₂, vitamin B₁₉, methionine supplementation, and betaine has been tried. Of these, early treatment with betaine seems to have the most beneficial effect.

The condition is inherited as an autosomal recessive trait; the gene for the enzyme has been located on chromosome 1p36.3 and many disease-causing mutations have been reported in the MTHFR gene. Prenatal diagnosis can be offered by measuring MTHFR enzyme activity in cultured chorionic villus cells or amniocytes, by linkage analysis in informative families, or by DNA analysis of the mutation.

**HYPERMETHIONINEMIA**

**Primary (Genetic) Hypermethioninemia**

Elevation of plasma level of methionine occurs in the following genetic conditions:

1. **Classic homocystinuria** (see above).
2. **Hepatic methionine adenosyltransferase (MAT I/MAT III) deficiency:** This enzyme, which has 2 isoforms, MAT I (tetrameric) and MAT III (dimeric), is encoded by a single gene (MAT 1A) and is involved in the first step of methionine catabolism (see Fig. 85-3). Another structurally similar enzyme, MAT II, is encoded by a different gene (MAT 2A on chromosome 2p11.2) and is expressed predominately in nonhepatic tissues (kidney, brain, lymphocytes). Deficiency of MAT I/MAT III causes hypermethioninemia without homocystinuria. The majority of these patients have been diagnosed in the neonatal period through screening for homocystinuria. Most affected individuals have residual enzyme activity and remain asymptomatic throughout life despite persistent hypermethioninemia. Some complain of an unusual offensive odor to their breath (boiled cabbage). A few patients with complete enzyme deficiency have had neurologic abnormalities related to demyelination (intellectual disability, dystonia, dyspraxia).

Laboratory studies reveal markedly elevated levels of plasma methionine with a low level of S-adenosylmethionine and normal concentrations of S-adenosylhomocysteine and homocysteine. These findings differentiate this condition from other causes of hypermethioninemia.

No uniformly accepted therapeutic regimen has yet emerged. Diets low in methionine result in lowering of plasma methionine, but the advisability of such diets has been questioned since lowering of the plasma methionine level causes further lowering of S-adenosylmethionine in the body.
3. **Glycine N-methyltransferase deficiency**: Although there are many methyltransferases present in the body, glycine N-methyltransferase is the critical one for catabolism of S-adenosylmethionine to S-adenosylhomocysteine (see Fig. 85-3). Three patients with deficiency of this enzyme have been reported to date. Clinically, patients were asymptomatic except for mild hepatomegaly and elevated serum levels of transaminases. Other laboratory findings included hypermethioninemia and very high...
levels of serum S-adenosylmethionine. No specific treatment has yet been identified. The condition seems to be inherited as an autosomal recessive trait; the gene for the enzyme (GNMT) is on chromosome 6p21.1.

4. **Adenosylhomocysteine hydrolase deficiency:** Deficiency of this enzyme (see Fig. 85-3) has been reported in 6 patients from 5 different families. Psychomotor retardation and severe hypotonia were common clinical findings in affected individuals. Laboratory studies included elevated levels of serum creatine kinase, hyperalbininemia (causing fetal hydrops in 1 family), hypophosphatemia, and markedly elevated levels of serum S-adenosylhomocysteine with moderate elevations of plasma methionine and S-adenosylmethionine. Marked elevation in S-adenosylhomocysteine has been thought to cause inhibition of methyltransferases, including those involved in synthesis of creatine (see Fig. 85-10) and choline, resulting in their deficiencies. MRI of the brain showed delayed myelination of the white matter. Treatment with a low methionine diet in conjunction with creatine and phosphatidylcholine shows encouraging results in some patients.

5. **Tyrosinemia type I** (see Chapter 85.2).

6. **Citrin deficiency** (see Chapter 85.12).

### Acquired (Nongenetic) Hypermethioninemia

Hypermethioninemia occurs in premature and some full-term infants receiving high-protein diets, in whom it may represent delayed maturation of the enzyme MAT. Lowering the protein intake usually resolves the abnormality. It is also commonly found in patients with various forms of liver disease.

### CYSTATHIONINEMIA (CYSTATHIONINURIA)

Secondary cystathioninuria occurs in patients with vitamin B6, or B12 deficiency, liver disease (particularly damage caused by galactosemia), thryrotoxicism, hepatoblastoma, neuroblastoma, ganglioblastoma, or defects in remethylation of homocysteine.

Cystathionase deficiency results in massive cystathioninuria and mild to moderate cystathioninemia; cystathionine is not normally detectable in blood. Deficiency of this enzyme is inherited as an autosomal recessive trait and its prevalence is estimated to be about 1 in 14,000 live births. Affects subjects with a wide variety of clinical manifestations have been reported. Lack of a consistent clinical picture and the presence of cystathioninuria in a number of individuals free of clinical findings suggest that cystathionase deficiency may be of no clinical significance. A majority of reported cases are responsive to oral administration of large doses of vitamin B6 (≥100 mg/24 hr). When cystathioninuria is discovered in a patient, vitamin B6 treatment seems indicated, but its beneficial effect has not been established. The gene encoding for cystathionase (CTH) is located on chromosome 16q31.1.

### Sulfite Oxidase Deficiency (Molybdenum Cofactor Deficiency)

At the last step in cysteine metabolism, sulfite is oxidized to sulfate by sulfite oxidase, and the sulfate is excreted in the urine (see Fig. 85-3). This enzyme requires a molybdenum-pterin complex named molybdenum cofactor. This cofactor is also necessary for the function of 2 other enzymes in humans: xanthine dehydrogenase (which oxidizes xanthine and hypoxanthine to uric acid) and aldehyde oxidase (involved in oxidizing a number of natural compounds and drugs). Three enzymes, encoded by 3 different genes (MOCS1, MOCS2, and SUOX) are involved in the synthesis of the cofactor. The genes for these enzymes are mapped to chromosomes 6p21.2, 5q11.2, and 14q23.3, respectively. Deficiency of any of the 3 enzymes causes cofactor deficiency with identical phenotype. Most patients, who were originally diagnosed as having sulfite oxidase deficiency, have been proven to have molybdenum cofactor deficiency. Both conditions are inherited as autosomal recessive traits. The gene for sulfite oxidase (SUOX) is on chromosome 12q13.2.

The enzyme and or the cofactor deficiencies produce identical clinical manifestations. Refusal to feed, vomiting, severe intractable seizures (tonic, clonic, myoclonic), cortical atrophy with subcortical multicystic lesions, and severe developmental delay may develop within a few weeks after birth. Bilateral dislocation of ocular lenses is a common finding in patients who survive the neonatal period. The intractable seizures seen in this condition are, in large part, a consequence of secondary vitamin B6 dependency. The accumulation of sulfites in body fluids in this condition causes the inhibition of antiguinuin enzyme which is necessary for conversion of α-aminoacidic semialdehyde to α-aminoacidic acid; the resultant accumulation of α-aminoacidic semialdehyde and its cyclic form P6C causes the inactivation of pyridoxal-5-phosphate (active form of vitamin B6) and, hence, the vitamin B6-dependent epilepsy (see also Chapter 85.14).

These children excrete large amounts of sulfite, thiosulfate, S-sulfocysteine, xanthine, and hypoxanthine in their urine. Urinary and serum levels of uric acid and urinary concentration of sulfate are diminished. Fresh urine should be used for screening purposes and for quantitative measurements of sulfite, because oxidation of sulfite to sulfate at room temperature may produce false-negative results. Increased concentrations of α-aminoacidic semialdehyde and its cyclic form, P6C, and piperacilic acid are present in the CSF, plasma, and urine.

**Diagnosis** is confirmed by measurement of sulfite oxidase and molybdenum cofactor in fibroblasts and liver biopsies, respectively or by DNA studies. Prenatal diagnosis is possible by performing an assay of sulfite oxidase activity in cultured amniotic cells, in samples of chorionic villi or by DNA studies.

No effective **treatment** is available; large doses of vitamin B6 (5-100 mg/kg) result in dramatic alleviation of seizures but do not seem to alter the devastating neurologic outcome. Most children die in the 1st 2 yr of life. One patient had an initial response to cyclic pyranopterin monophosphate (cFMP). The prevalence of these deficiencies in the general population is not known.

**Bibliography is available at Expert Consult.**

### 85.5 Tryptophan

**Iraj Rezvani**

Tryptophan is an essential amino acid and a precursor for nicotinic acid (niacin) and serotonin (Fig. 85-5). The genetic disorders of metabolism of serotonin, one of the major neurotransmitters, are discussed in Chapter 85.11.

### HARTNUP DISORDER

In this autosomal recessive disorder, named after the first affected family, there is a defect in the transport of monoamino-monocarboxylic amino acids (neutral amino acids), including tryptophan, by the intestinal mucosa and renal tubules. The transporter protein for these amino acids (B0AT1) is encoded by the SLC6A19 gene located on chromosome 5p15.33. Two chemically close transcription factors, angiotensin-converting enzyme (ACE2) in the intestine and renal tubules, and collectrin in the renal tubules, are required for expression of B0AT1 transporter protein by the SLC6A19 gene. The mutated gene in patients with Hartnup disorder, unable to interact with the above...
Bibliography

Defects in Metabolism of Amino Acids

Bibliography

transcription factors, results in deficiency of B0AT1 protein either in the intestine or in the renal tubules or in both. This explains the absence of renal or intestinal transport defect seen in some affected families. Decreased intestinal absorption of tryptophan in conjunction with its increased renal loss is believed to cause reduced availability of tryptophan for niacin synthesis in affected individuals. Most children with Hartnup disorder remain asymptomatic. The major clinical manifestation in the rare symptomatic patient is cutaneous photosensitivity. The skin becomes rough and red after moderate exposure to the sun, and with greater exposure, a pellagra-like rash may develop. The rash may be pruritic, and a chronic eczema may develop. The skin changes have been reported in affected infants as young as 10 days of age. Some patients may have intermittent ataxia manifested as an unsteady, wide-based gait. The ataxia may last a few days and usually recovers spontaneously. Mental development is usually normal. Two individuals in the original kindred were cognitively impaired. Episodic psychiatric manifestations such as irritability, emotional instability, depression, and suicidal tendencies, have been observed; these changes are usually associated with bouts of ataxia. Short stature and atrophic glossitis are seen in some patients.

Most children diagnosed with Hartnup disorder by neonatal screening have remained asymptomatic. This indicates that other factors are also involved in pathogenesis of the clinical condition.

The main laboratory finding is aminoaciduria, which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine). Urinary excretion of proline, hydroxyproline, and arginine remains normal. This finding differentiates Hartnup disorder from other causes of generalized aminoaciduria, such as Fanconi syndrome. Plasma concentrations of neutral amino acids are usually normal. This seemingly unexpected finding occurs because these amino acids are absorbed as dipeptides and the transport system for small peptides is intact in Hartnup disorder. The indole derivatives (especially indican) may be found in large amounts in some patients, owing to bacterial breakdown of unab sorbed tryptophan in the intestines.

Diagnosis is established by the striking intermittent nature of symptoms and the previously described urinary findings.

Treatment with nicotinic acid or nicotinamide (50-300 mg/24 hr) and a high-protein diet results in a favorable response in symptomatic patients. Because of the intermittent nature of the clinical manifestations, the efficacy of these treatments is difficult to evaluate. The prevalence of the disorder is estimated to be 1 in 20,000 to 1 in 30,000 live births. Normal outcome both for mother and fetus is reported in affected pregnant women.

Bibliography is available at Expert Consult.

---

85.6 Valine, Leucine, Isoleucine, and Related Organic Acidemias

Iraj Rezvani and David S. Rosenblatt

The early steps in the degradation of these 3 essential amino acids, the branched-chain amino acids, are similar (see Fig. 85-4). The intermediate metabolites are all organic acids, and deficiency of any of the degradative enzymes, except for the transaminases, causes acidosis; in such instances, the organic acids proximal to the enzymatic block accumulate in body fluids and are excreted in the urine. These disorders commonly cause metabolic acidosis, which usually occurs in the first few days of life. Although most of the clinical findings are nonspecific, some manifestations may provide important clues to the nature of the enzyme deficiency. Figure 85-6 presents an approach to infants suspected of having an organic acidemia. Definitive diagnosis is usually established by identifying and measuring specific organic acids in body fluids (blood, urine), by the enzyme assay, and by identification of the mutant gene.

Organic acidemias are not limited to defects in the catabolic pathways of branched-chain amino acids. Disorders causing accumulation of other organic acids include those derived from lysine (see Chapter 85.14), those associated with lactic acid (see Chapter 87), and dicarboxylic acidemias associated with defective fatty acid degradation (see Chapter 86.1).

MAPLE SYRUP URINE DISEASE

Decarboxylation of leucine, isoleucine, and valine is accomplished by a complex enzyme system (branched-chain α-ketoacid dehydrogenase [BCKDH]) using thiamine (vitamin B1) pyrophosphate as a coenzyme. This mitochondrial enzyme consists of 4 subunits: E1α, E1β, E2, and E3. The E2 subunit is shared with 2 other dehydrogenases in the body, namely pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Deficiency of any of these subunits causes maple syrup urine disease (MSUD) (see Fig. 85-4), named after the sweet odor of maple syrup found in body fluids, especially urine. Clinical conditions caused by defects in E1α, E1β, E2, and E3 are designated as MSUD type IA, type IB, type 2, and type 3 respectively. This classification, however, is not very helpful clinically because the severity of clinical manifestations does not correlate with or correspond specifically to any single type. An affected infant with type 1A defect can have clinical manifestations ranging from relatively mild to very severe. A more useful classification, based on clinical findings and response to thiamine administration, has identified 5 phenotypes of MSUD as follows:

---

Figure 85-5 Pathways in the metabolism of tryptophan. PKU* indicates hyperphenylalaninemia caused by tetrahydrobiopterin deficiency (see Fig. 85-1). Enzymes: (1) Tryptophan hydroxylase, (2) aromatic l-αmino acid decarboxylase (AADC), (3) monoamine oxidase (MAO).
Bibliography
Clinical approach to MSUD, to infants

Soon as possible so as to reverse the patient's catabolic state. Cerebral calories and nutrients should be provided intravenously or orally as of therapy in critically ill infants and should be instituted promptly; peritoneal dialysis or, preferably, hemodialysis is the most effective mode is poor, hydration alone may not produce a rapid improvement. Peri-
imaging of the brain. The enzyme activity can be measured in leukocytes ing age, hypomyelination and cerebral atrophy may be seen in neuro-

terminal capsule. After recovery from the acute state and with advanc-

ing during the acute state may show cerebral edema, which is most prominent in the cerebellum, dorsal brainstem, cerebral peduncle, and prominence in the interictal period.

Generalized seizures and coma may ensue within a few days. Physical examination reveals hypotonia and muscular rigidity with severe opisthotonus. Periods of hypotonia may alternate with bouts of flaccidity manifested as repetitive movements of the extremities (boxing and bicycling). Neurologic findings are often mistakenly thought to be caused by generalized spasticity and meningitis. Cerebral edema may be present; convulsions occur in most infants, and hypo-
glycemia is common. In contrast to most hypoglycemic states, correction of the blood glucose concentration does not improve the clinical condition. Aside from the serum glucose, routine laboratory findings are usually unremarkable, except for varying degrees of metabolic acido-

osis. Death usually occurs in untreated patients in the first few weeks or months of life.

Diagnosis is often suspected because of the peculiar odor of maple syrup found in urine, sweat, and cerumen (see Fig. 85-6). It is usually confirmed by amino acid analysis showing marked elevations in plasma levels of leucine, isoleucine, valine, and alloisoleucine (a stereo-specific isomer of isoleucine not normally found in blood) and depression of alanine. Leucine levels are usually higher than those of the other 3 amino acids. Plasma concentrations of leucine, isoleucine, and valine and their respective ketoacids. These ketoacids may be detected qualitatively by adding a few drops of 2,4-dinitrophenylhydrazine reagent (0.1% in 0.1N HCl) to the urine; a yellow precipitate of 2,4-dinitrophenylhydrazone, is formed in a positive test. Neuroimag-
ing during the acute state may show cerebral edema, which is most prominent in the cerebellum, dorsal brainstem, cerebral peduncle, and internal capsule. After recovery from the acute state and with advancing age, hypomyelination and cerebral atrophy may be seen in neuro-

imaging of the brain. The enzyme activity can be measured in leukocytes and cultured fibroblasts.

Treatment of the acute state is aimed at hydration and rapid removal of the branched-chain amino acids and their metabolites from the tissues and body fluids. Because renal clearance of these compounds is poor, hydration alone may not produce a rapid improvement. Peri-
toneal dialysis or, preferably, hemodialysis is the most effective mode of therapy in critically ill infants and should be instituted promptly; significant increases in plasma levels of leucine, isoleucine, and valine are usually seen within 24 hr of institution of treatment. Sufficient calories and nutrients should be provided intravenously or orally as soon as possible so as to reverse the patient's catabolic state. Cerebral edema, if present, may need to be treated with mannitol, diuretics (e.g., furosemide), or hypertonic saline.

Treatment after recovery from the acute state requires a diet low in branched-chain amino acids. Synthetic formulas devoid of leucine, isoleucine, and valine are available commercially. Because these amino acids cannot be synthesized endogenously, small amounts of them should be added to the diet; the amount should be titrated carefully by performing frequent analyses of the plasma amino acids. A clinical condition resembling acrodermatitis enteropathica (see Chapter 671) occurs in affected infants whose plasma isoleucine concentration becomes very low; addition of isoleucine to the diet causes a rapid and complete recovery. Patients with MSUD should remain on the diet for the rest of their lives. Liver transplantation has been performed in a number of patients with classic MSUD with promising results. These children have been able to tolerate a normal diet.

The long-term prognosis of affected children remains guarded. Severe ketoacidosis, cerebral edema, and death may occur during any stressful situation such as infection or surgery, especially in mid-

childhood. Cognitive and other neurologic deficits are common sequelae.

Intermediate (Mild) Maple Syrup Urine Disease

In this form, affected children develop milder disease after the neonatal period. Clinical manifestations are insidious and limited to the CNS. Patients have mild to moderate intellectual disability (usually after 5 mo of age) with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the branched-chain amino acids and their ketoacid derivatives in the urine. In this form, affected children develop milder disease after the neonatal period. Clinical manifestations are insidious and limited to the CNS. Patients have mild to moderate intellectual disability (usually after 5 mo of age) with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the branched-chain amino acids and their ketoacid derivatives in the urine. Plasma concentrations of leucine, isoleucine, and valine are moderately increased whereas those of lactate and pyruvate are normal. These children are commonly diagnosed during an intercurrent illness when signs and symptoms of classic MSUD may occur. The dehydrogenase activity is 3-40% of normal. Because patients with thiamine-responsive MSUD usually have manifestations similar to those seen in the mild form, a trial of thiamine therapy is recommended. Diet therapy, similar to that of classic MSUD, is needed.

Intermittent Maple Syrup Urine Disease

In this form of MSUD, seemingly normal children develop vomiting, odor of maple syrup, ataxia, lethargy, and coma during any stress or catabolic state such as infection or surgery. During these attacks, labor-
atory findings are indistinguishable from those of the classic form, and death may occur. Treatment of the acute attack of intermittent

**Figure 85-6** Clinical approach to infants with organic acidemia. Asterisks indicate disorders in which patients have a characteristic odor (see text and Table 85-2). MSUD, maple syrup urine disease.
MSUD is similar to that of the classic form. After recovery, although a normal diet is tolerated, a diet low in branched-chain amino acids is recommended. Activity of the dehydrogenase in patients with the intermittent form is higher than in the classic form and may reach 40% of the normal activity.

**Thiamine-Responsive Maple Syrup Urine Disease**

Some children with mild or intermediate forms of MSUD who are treated with high doses of thiamine have dramatic clinical and biochemical improvement. Although some respond to treatment with thiamine at 10 mg/24 hr, others may require as much as 200 mg/24 hr for at least 3 wk before a favorable response is observed. These patients also require diets deficient in branched-chain amino acids. The enzymatic activity in these patients is 30–40% of normal.

**Maple Syrup Urine Disease Caused by a Deficiency of E$_2$ Subunit (Maple Syrup Urine Disease Type 3)**

This is a very rare disorder. Patients develop lactic acidosis in addition to signs and symptoms similar to those of intermediate MSUD because the E$_2$ subunit is also a component of pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Progressive neurologic impairment manifested by hypotonia and developmental delay occurs after 2 mo of age. Abnormal movements progress to ataxia. Death may occur in early childhood.

**Laboratory findings** include persistent lactic acidosis with high levels of plasma lactate, pyruvate, and alanine. Plasma concentrations of branched-chain amino acids are moderately increased. Patients excrete large amounts of lactate, pyruvate, α-glutamate, and the 3-branched-chain ketoacids in their urine.

No effective treatment is available. Dietary restrictions of branched-chain amino acids and treatment with high doses of thiamine, biotin, and lipoic acid have been ineffective.

**Genetics and Prevalence of Maple Syrup Urine Disease**

All forms of MSUD are inherited as an autosomal recessive trait. The gene for each subunit resides on different chromosomes. The gene for E$_{1a}$ (BCKDHA) is on chromosome 19q13.1-q13.2; that for E$_{1b}$ (BCKDHB) is on chromosome 6q14.1; the gene for E$_{2}$ (DBT) is on chromosome 1p21.2; and that for E$_{3}$ (DDL) is on chromosome 7q31.1. Many different disease-causing mutations (>160) have been identified in patients with different forms of MSUD. A given clinical phenotype is caused by a variety of genotypes; an example, patients from different pedigrees with the classic form of MSUD have been shown to have mutations in genes for E$_{1a}$, E$_{1b}$, or E$_{2}$ subunits. The exception is the thiamine-responsive MSUD that is known to be caused by mutations in the E$_{2}$ gene in all reported cases to date. Most patients are compound heterozygotes inheriting 2 different mutant alleles. Mutations in genes for E$_{1a}$ (45%) and E$_{1b}$ (35%) account for approximately 80% of cases.

The prevalence is estimated at 1 in 185,000 live births. The classic form of MSUD is more prevalent in the Old Order Mennonites in the United States (in the United States). Isovaleric acidemia is inherited as an autosomal recessive trait (see Chapter 84). Isovaleryl CoA dehydrogenase (see Fig. 85-4). Clinically, two forms of the condition are recognized in symptomatic patients: the acute form and the chronic intermittent form.

**ISOOVALERIC ACIDEMIA**

This condition is caused by the deficiency of the enzyme isovaleryl CoA dehydrogenase (see Fig. 85-4). Clinically, two forms of the condition are recognized in symptomatic patients: the acute form and the chronic intermittent form.

**Clinical manifestations** in the acute form include vomiting and severe acidosis in the first 2 wk of life. Lethargy, convulsions, and coma may ensue, and death may occur if proper therapy is not initiated. The vomiting may be severe enough to suggest pyloric stenosis. The characteristic odor of “sweaty feet” may be present (in body sweat and corns, but not in the urine; see Fig. 85-6). Infants who survive this acute episode will go on to have the chronic intermittent form later in life. In the chronic intermittent form of the disease, the first clinical manifestations (vomiting, lethargy, acidosis or coma) may not appear until the child is a few months or a few years old. In both forms, acute episodes of metabolic decompensations may occur during a catabolic state such as an infection. Acute episodes may be mistaken for diabetic ketoacidosis. With worldwide application of newborn screening technology (see Chapter 84) it is now becoming clear that the clinical spectrum in affected patients can range from completely asymptomatic to the acute form. Older siblings of symptomatic newborn infants have been reported with identical genotype and biochemical abnormalities but without any clinical manifestations.

**Laboratory findings** during the acute attacks include ketoacidosis, neutropenia, thrombocytopenia, and occasionally pancyclopentenia. Hypocalcemia, hyperglycemia, and moderate to severe hyperammonemia may be present in some patients. Increases in plasma ammonia may suggest a defect in the urea cycle (see Chapter 85.12). In urea cycle defects, the infant is not acidic (see Fig. 85-6).

**Diagnosis** is established by demonstrating marked elevations of isovaleric acid and its metabolites (isovalerylglucine, 3-hydroxyisovaleric acid) in body fluids, especially urine. The main compound in plasma is isovalerylcarnitine, which can be measured even in a few drops of dried blood on a filter paper. Diagnosis can be confirmed by measurement of the enzyme activity in cultured skin fibroblasts or by the identification of the mutant gene.

**Treatment** of the acute attack is aimed at hydration, reversal of the catabolic state (by providing adequate calories orally or intravenously), correction of metabolic acidosis (by infusing sodium bicarbonate), and removal of the excess isovaleric acid. Because isovalerylglucine has a high urinary clearance, administration of glycine (250 mg/kg/24 hr) is recommended to enhance formation of isovalerylglucine. L-Carnitine (100 mg/kg/24 hr orally) also increases removal of isovaleric acid by forming isovaleryl carnitine, which is excreted in the urine. In patients with significant hyperammonemia (blood ammonia >200 μM), measures that reduce blood ammonia should be employed (see Chapter 85.12). Exchange transfusion and peritoneal dialysis may be needed if the previously described measures fail to induce significant clinical and biochemical improvement. After recovery from the acute attack, the patient should receive a low-protein diet (1.0-1.5 g/kg/24 hr) and should be given glycine and carnitine supplements. Pancreatitis (acute or recurrent forms) has been reported in survivors. Normal development can be achieved with early and proper treatment.

Prenatal diagnosis may be accomplished by measuring isovalerylglucine in amniotic fluid, by enzyme assay in cultured amniocytes, or by identification of the mutant gene. Successful pregnancy with favorable outcomes both for the mother and the infant has been reported.

**MULTIPLE CARBOXYLASE DEFICIENCIES**

**DEFECTS IN UTILIZATION OF BIOTIN**

Biotin is a water-soluble vitamin that is a cofactor for all 4 carboxylase enzymes in humans: pyruvate carboxylase, acetyl CoA carboxylase,
propionyl CoA carboxylase, and 3-methylcrotonyl CoA carboxylase. The latter 2 are involved in the metabolic pathways of leucine, isoleucine, and valine (see Fig. 85-4).

Dietary biotin is bound to proteins; free biotin is generated in the intestine by the action of digestive enzymes, by intestinal bacteria, and perhaps by biotinidase. The latter enzyme, which is found in serum and most tissues in the body, is also essential for the recycling of biotin in the body by releasing it from the apoenzymes (carboxylases; see Fig. 85-4). Free biotin must form a covalent peptide bond with the apoprotein of the 4 carboxylases to form the activated enzyme (holocarboxylase). This binding is catalyzed by holocarboxylase synthetase. Deficiencies in this enzyme activity or in biotinidase result in malfunction of all the carboxylases and in organic acidaemia.

**Holocarboxylase Synthetase Deficiency (Multiple Carboxylase Deficiency Neonatal or Early Form)**

Infants with this rare autosomal recessive disorder become symptomatic in the first few weeks of life. Symptoms may appear as early as a few hours after birth to 21 mo of age. Clinically, the affected infants who seem normal at birth develop breathing difficulties (tachypnea and apnea) shortly after birth. Feeding problems, vomiting, and hypotonia are also commonly present. If the condition remains untreated, generalized erythematous rash with exfoliation and alopecia (partial or total), failure to thrive, irritability, seizures, lethargy, and even coma may occur. Developmental delay is common. Immune deficiency manifests with susceptibility to infection. The urine may have a peculiar odor, which has been described as similar to tomcat urine. The rash, when present, differentiates this condition from other organic acidaemias (see Fig. 85-6).

**Laboratory findings** include metabolic acidosis, ketosis, hyperammonemia, and the presence of a variety of organic acids (lactic acid, propionic acid, 3-methylcrotonic acid, 3-methylcrotonylglycine, tiglylglycine, methylcitrate, and 3-hydroxyisovaleric acid) in body fluids. Diagnosis is confirmed by the enzyme assay in lymphocytes or cultured fibroblasts or by identification of the mutant gene. Most mutations cause the enzyme to have an increased $K_m$ (Michaelis-Menten dissociation constant) for biotin; the enzyme activity in such patients can be restored by the administration of large doses of biotin.

**Treatment** with biotin (10 mg/day orally) usually results in an improvement in clinical manifestations and may normalize the biochemical abnormalities. Early diagnosis and treatment are critical to prevent irreversible neurologic damage. In some patients, however, complete resolution may not be achieved even with large doses (up to 80 mg/day) of biotin.

The gene for holocarboxylase synthetase (HLCS) is located on chromosome 21q22.1 and many disease-causing mutations have been identified in different families. Prenatal diagnosis has been accomplished by assaying enzyme activity in cultured amniotic cells and by measurement of intermediate metabolites (3-hydroxyisovalerate and methylcitrate) in amniotic fluid or by DNA analysis. Pregnant mothers who had previous offspring with holocarboxylase synthetase deficiency have been treated with biotin late in pregnancy. Affected infants were normal at birth, but the inefficacy of the treatment as related to the outcome remains unclear.

**Biotinidase Deficiency (Multiple Carboxylase Deficiency—Juvenile or Late Form)**

The absence of biotinidase results in biotin deficiency. Infants with this deficiency may develop clinical manifestations similar to those seen in infants with holocarboxylase synthetase deficiency but, unlike the latter, symptoms may appear later when the child is several months or years old; symptoms may develop as early as 1 wk of age. Therefore, the term “late form” does not apply to all cases and can be misleading. The delay is presumably because of the presence of sufficient free biotin derived from the mother or the diet. Clinical manifestations are mostly confined to skin and the nervous system. Atopic or seborrheic dermatitis, candidiasis, alopecia, ataxia, seizures (usually myoclonic type), hypotonia, developmental delay, optic atrophy, sensorineural hearing loss, and immunodeficiency (from T-cell abnormalities) may occur. A small number of children with intractable seborrheic dermatitis and partial (15-30% activity) deficiency of the enzyme, in whom the dermatitis resolved with biotin therapy, have been reported; these children were otherwise asymptomatic. Asymptomatic children and adults with this enzyme deficiency have been identified in screening programs. Most of these individuals have been shown to have partial deficiency of the enzyme activity. With the advent of mass screening of newborn infants and early identification and treatment of the affected patients, the clinical disease is predicted to become extinct.

**Laboratory findings** and the pattern of organic acids in body fluids resemble those associated with holocarboxylase synthetase deficiency (see above). Diagnosis can be established by measurement of the enzyme activity in the serum or by the identification of the mutant gene.

**Treatment** with free biotin (5-20 mg/24 hr) results in a dramatic clinical and biochemical response. Treatment with biotin is also suggested for individuals with partial biotinidase deficiency.

The prevalence of this autosomal recessive trait is estimated at 1 in 60,000 live births. The gene for biotinidase (BTD) is located on chromosome 3p25.1 and many disease-causing mutations (approximately 150) have been identified in different families. Prenatal diagnosis is possible by the measurement of the enzyme activity in the amniotic cells or by identification of the mutant gene.

**Multiple Carboxylase Deficiency Because of Dietary Biotin Deficiency**

Acquired deficiency of biotin may occur in infants receiving total parenteral nutrition without added biotin, in patients receiving prolonged anticonvulsant drugs (phenytoin, primidone, carbamazepine) or in children with short bowel syndrome or chronic diarrhea who are receiving formulas low in biotin. Excessive ingestion of raw eggs may also cause biotin deficiency because the protein avidin in egg white binds biotin and makes it unavailable for absorption. Infants with biotin deficiency may develop dermatitis, alopecia, and candidal skin infections.

**ISOLATED 3-METHYLacrotyonyL COENZYME A (CoA) CARBOXYLASE DEFICIENCY**

This enzyme is 1 of 4 carboxylase enzymes in the body that require biotin as a cofactor (see Fig. 85-4). An isolated deficiency of this enzyme must be differentiated from disorders of biotin metabolism (multiple carboxylase deficiency), which causes diminished activity of all 4 carboxylases (see above). 3-Methylcrotonyl CoA carboxylase is a heteroergic enzyme consisting of α (biotin containing) and β subunits.

**Clinical manifestations** are highly variable, ranging from fatal neonatal onset (seizures, hypotonia, acidosis) to completely asymptomatic adults (including mothers of affected newborn infants). In the severe form of the condition, the affected infant who has been seemingly normal develops an acute episode of vomiting, hypotonia, lethargy, and convulsions after a minor infection. The onset is usually between 3 wk and 3 yr of age. Death may occur during the acute episode.
